From our diversion upon De Quincey and his opium eating, let us turn, as we promised, to the effects of the "mystic drug" in restraining the *diuresis* of fear and anxiety. We have given sufficient cases in point and in proof, and we have others to give drolly illustrative of unexpected consequences:—but first, let us inquire into the cause of the thing, or to speak technically, let us investigate the *modus operandi*. How does opium act in restraining the diuretic effects of trepidation? It is known to diminish all the secretions, except those of the skin and the mammæ, when taken habitually; and therefore, if swallowed some hours prior to the occasion of excitement, its action might be accounted for on the supposition that it had blunted the nervous sensibility of the kidneys, and deadened them to the influence of casual or accustomed impressions. Analogical effects would be observed upon the brain, the organs of sense, and the salivary glands. The ideas would be confused, clouded, or slow—vision, hearing, smell, and taste, would be diminished or depraved—and the tongue would roll listlessly in a parched and fevered mouth. An obvious and common cause would account for all these effects—they would be severally traceable to a subsidence, more or less complete, of healthy innervation. But an opposite consequence results from a *recent* dose of opium—the pulse and the respiration are quickened—the ideas become more energetic and active—and the whole system partakes of the stimulus. Why, with this accelerated circulation, this temporary excitement, in which the kidneys participate in common with other organs, do they not respond with an increase of secretion? They are comparatively inactive, and yet without any increased perspiration being supplemental of their discharge. It seems to be, that the stimulated brain not only diverts the common organic functions of the body in the majority of cases, but in others, should these functions proceed uninterruptedly, the brain is insensible to the results of their activity. Not insensible from the *absence* of excitement, but from the *excess* of it. To the performance of a voluntary function, it is necessary that the brain take cognizance of the condition of the organ immediately implicated in such function, and that *volition* respond to the organic necessity. The response may be withheld from an inability on the part of the brain to *receive* the impression, and consequently, to *answer* to it—from an intentional resistance of the impression, and from the mind being so occupied and absorbed by other thoughts, that there is no *perception* of a state of organic embarrassment. In apoplexy, for instance, the kidneys may continue to secrete, and the bladder become slowly distended to the full, without the brain being *conscious* of its distress—in another case, and in a limited degree, a desire to retain the urine may control the physical inducement to its expulsion—and in a third, a diversion of thought may produce the same effect to an unmeasured extent. The enlarged prostate, the paralysed bladder, and the hemorrhoids, so prevalent amongst literary men, lawyers, clergymen, and statesmen, are chiefly due to the frequency with which the urine is copiously secreted and accumulated without the sufferer being sensible of his distressing state. A man who, at one time having no particular object to divert his thoughts, will be perpetually urinating, at another, his mind being intently occupied, will be totally unconscious of a distended bladder. It is not an uncommon thing for a minister at the termination of public service, or a barrister at the close of a lengthened address, or a mathematician after a fit of intense abstraction, to become suddenly sensible of an impression upon the bladder, which he did not in the least perceive during his mental diversion. The impression is sometimes so strong as to be totally irresistible, and the occasion of most unpleasant consequences—for directly that the *perception* of the physical distress becomes complete, and *ideas* are established upon it, voluntary control is generally at an end. It is thus that an anomaly of drunkenness may be accounted for. A man will tell you that he was quite sober when he left the table, but became dizzy and intoxicated directly that he got into the street. The fact is, his thoughts were variously exercised and directed by the presence and conversation of his friends, and he not only was not sensible of his state, but the very occupation of his mind in some measure restrained the development of the effects of the alcohol upon it. But directly that he is alone, one stimulus being withdrawn, the other becomes paramount, and the involuntary, unmanageable ideas of drunkenness supersede the rational ones of sobriety. Supply another stimulus, physical or mental, and reason again assumes the mastery. The new excitement supplants the one already existing—in reality, *counteracts* it. Thus, whilst one form of stimulation deranges the mind, another restores it to reason—and so, *similia similibus curantur*. Give an intoxicated man a good dose of ammonia, and ten to one but he will become sober in a few minutes—let another be attacked by a bull, or a savage dog, and he will quickly recover the use of his legs—or a third fall into a chilling stream, and he will scramble ashore with little remnant of inebriety in him. We once saw a man reeling under a most influential load of liquor, along the banks of a river running through a hay field. After sundry gyrations, he plumped head first into the water. We were amongst others who ran with forks and rakes to help him out, but from the peculiarity of the situation, he was not landed without much trouble, and a most thorough ducking. Such, however, was the soberising effect upon him, that directly he regained his legs, he coolly felt all his pockets, and finding his spectacles were missing, with much difficulty and dexterity fished them out of the water with a rake, and then walked off as steady and perpendicular as a soldier on drill. We once witnessed a case exactly the opposite of this; but equally illustrative of the position we have advanced. It was in the person of a gentleman, who during the terminating innings of a great cricket match, was both drinking and betting heavily. He was backing the innings side—their last man was in, and only a few notches remained to be scored. The play was admirably cautious on both sides, and even the spectators who had nothing at stake, were breathless with anxiety. As each "over" was bowled, the interest was heightened with every looker-on, but especially with him above mentioned. He was roused to the highest pitch of enthusiastic hope, and cheered and shouted vehemently. Notch after notch was slowly scored, till at last but one remained—victory

was all but certain—the bets were all but sure—when a terrific "shooter" from Mr. Mynn ripped up the stumps so gallantly defended, and in a moment, luck changed hands. In less time than we take to tell it, the man who before had been merry, lively and expectant, dropped upon his chair dead drunk and stertorous. He did not revive for hours. In his case, so long as excitement sustained him, he was for the most part proof against the effects of the wine he swallowed—directly that the excitement fell, and it was instantly, drunkenness became dominant, and it would have been no wonder had apoplexy finished the adventure.

Instances analogous of the above, are those in which tic doloureux, or tooth ache, is dispelled by fear, or by strong mental excitement, and labour pains are induced by one form of emotion, and interrupted by another. Nothing is more common than for sudden fright, or surprise, to curtail or to cure an attack of nervous pain. A gentleman, who for years had been a martyr to *neuralgia faciei*, which was the cause of much irritability and ill-temper, in one of his attacks committed an insult for which he was immediately knocked down. From that moment his pain left him, and he had no subsequent return of it. An eccentric London surgeon cured a similar case, by dashing, unexpectedly, a jug of cold water in a lady's face. The experiment was not equally satisfactory, for the dowager lost the pain and the doctor the patient, at the same time. A dread of the dentist's "key," at the moment of its application, is often a means of silencing tooth-ache for ever. Anxiety, fear, and fatigue, are a common cause of premature labour—and conversely, labour naturally begun, is frequently diverted for many hours or days, by the mental impression occasioned by the visit of the accoucheur. Opium is capable of producing either of these effects—it may expedite or intercept labour, according as it proves to be a sedative or stimulant. Be it understood, however, that we use the term *sedative* in a qualified sense. Whenever opium accelerates labour, it is by allaying a pain or spasm which may be interrupting it, in which case it no more deserves to be considered a sedative, properly so called, than when, on unlocking the intestines of a like spasm, and thus allowing their natural motion, it deserves to be called a cathartic. Usually, as we have said, it is a stimulant, and in restraining the diuresis of trepidation, it is by acting upon the brain in such wise, that, either this excited organ shall limit the action of the kidneys, or by diversion, be unconscious of the extent and effects of their produce.

We have said that opium must be taken very discreetly prior to a public appearance, or its effects upon the brain may be worse than those of fear upon the kidneys. Mr. —— was elected to the Presidency of the Hunterian Society of Edinburgh. He was a capital speaker, and the room was crowded on the occasion of his having to deliver his inaugural address. He was in the regular habit of taking opium before speaking in public, but in this instance it seems a greater anxiety prompted a greater dose. He took the chair with an unusually solemn and sedate look, and sat in singular quiet during the transaction of preparatory business. This finished, eyes and ears were all open to the *debut* of the favourite president. After the lapse of a few minutes, during which he showed no inclination to stir, a loud and prolonged snore declared him to be fast asleep. He was roused with some difficulty, "to a sense of his situation," but it was only to utter the most slow and stupid speech that ever fell from his lips. Another man in the same society, who was in the habit of like indulgence, added an irresistible mirth to the debate of an evening, by roaring out lustily, whilst in an unlucky slumber, "We wont go home till morning!" "Encore!" He had come as fully primed with his speech as with his opiate, but on afterwards rising to deliver it, he was received with a shout of laughter which drove him discomfited from the room. Mr. ——, a crack man of the "Medical," and one of its anticipated presidents, went to the society on the last evening prior to election, with the intention of making a telling speech which had cost him no little preparation and study. He did not scruple to say that he intended to do his best. and many were the members who expected to be treated to an unusual feast of oratory. The night through, he was listened and looked for, and all thought that what seemed to be slumber, was neither more nor less than profound reflection. One speaker after another finished—time wore away—there was a long pause—the chair inquired whether there were any other speakers—no answer—the meeting was declared to be over. Poor ——, who all this time had been asleep from an unusual dose of opium, was awakened to learn the annoying intelligence that his chance was gone. Mr. H. was invited to a soiree at Sir Charles ——'s. He was so much in the habit of taking opium before going to debating societies, that he could not even frequent ordinary parties without a similar preparation. On the night alluded to, he took an extra dose, from a desire to be more than ordinarily brilliant. He got over the early part of the evening pretty well, but during a pause in the more active entertainments, he fell fast asleep. Dreaming he was at a favourite café, whose head waiter bore the same name as the host of the evening, he suddenly astounded the assembly by jumping up from his sleep, and calling in a loud tavern tone—"Charles, look quick, will you? Bring a bottle of soda water, and my bill!"

MONOMANIA.

The trial of Martha Brixey for murder, at the Old Bailey, on the 16th instant, makes public another instance of that singular species of mania under whose sudden influence, worthy persons have been irresistibly impelled to monstrous acts of absurd cruelty. The prisoner, as our readers know, was a nursemaid, noticed for the kindness with which she treated the children in her charge. For some time she had been under medical treatment, apparently for amenorrhœa; had complained of curious headaches, and three days before the homicide, had exhibited an extraordinary fit of absurd passion about a trifle. On the day before, she was in a very excited condition, through the fear of being discharged by her mistress; talked about hanging and murder, and her preference of the former to imprisonment in a madhouse. On the day of the homicide, she was in the kitchen with one of the children, a girl; she entered the adjoining pantry, and returned thence with an ordinary table-knife. She was asked her intent, and answered, that she was about to cut a pencil for the child. When recommended a smaller knife, she took it, but with an ingenious reason retained the larger. She tried its edge between her finger and thumb—took both knives up stairs, and in a short time she descended—entered the parlour in grief—exclaimed to the child's father, that she had done something horrible—had "murdered the dear baby." The child's head was nearly dissevered from the body. A few incoherent expressions to the policeman, who took her in his custody, about a woman ever being hung, and what they would do with her—completed the whole evidence. The judge, Lord Denman, gave no decisive opinion, and the jury found, that the prisoner was "not responsible," and consequently acquitted her.

We need not trouble our readers with the mention of the numerous cases recorded, in which acts of murder have been committed under a sudden access of mania. It is sufficient to say, that while medical men have slowly been coming round to the conviction, that an act of atrocity may be the very first symptom of a deranged mental organ—the lawyers have persisted in maintaining the principle, that no circumstances in the monstrous tragedy itself shall be held sufficient in law to establish lunacy in the perpetrator. The diversity of opinion is not difficult to comprehend. Medical men regard the question solely on physiological grounds; jurisconsults pay more attention to the effects likely to arise from a conviction or acquittal. The one class look solely to the patient—the other to society, and while *we*, in a doubt about responsibility, would *save*—*they*, in the same situation, would sacrifice a prisoner.

In the case before us, however, there was no practical dissidence of judgment. The conduct of the prisoner before and after the homicide, made very *probable* the insanity which the additional circumstances of the act itself made certain, and the evidence altogether went very plainly to show, that if the law allows impunity to no wrong committed *as a wrong*, the unfortunate Martha Brixey was not in that state of mind in which she could distinguish the moral qualities of the homicide she was impelled to.

THE USE AND ABUSE OF CORONERS.

The *Gateshead Observer* has taken up this important subject with great zeal and ability, pledging itself not to cease labouring till a reform be introduced. The example is worth being followed by the whole Press—Provincial and Metropolitan. The subject is interesting under every aspect, and very inviting to a good man's labour. So clumsy, so disgraceful, so mischievous an anomaly in English jurisprudence as our "Crowner's Quest Law" must speedily find its term, if vigorously attacked by those whose highest duty and privilege it is to abate social nuisances. The following remarks by our clever contemporary cannot be too widely circulated:—

"It will be remembered that Sarah Freeman, a young widow, was executed at Taunton, shortly after these assizes, for the murder of her brother, Charles Dimond, by arsenic. This miserable woman had destroyed by poison, first her husband, next her child, then her mother, and finally her brother. There is also too much reason to believe that she had murdered several other perons by the same diabolical means.

"How was it that she ran her long and destructive career of crime without earlier detection? We have said, and we say again, that the office of coroner is responsible for such impunity—that, as at present constituted, it is a protection to the criminal, and not to society—that "coroners' inquests (in the words of the Medical Times) shield off, under their pretended performances, that duty of searching inquiry, which is the public's greatest safeguard in these days of daring and venturesome tranquillity." Let us see how far these assertions are borne out by the case of Sarah Freeman.

"It was in the month of November, 1843, that her illegitimate child, James Dimond, died. An

inquest was held a few days after death, and a medical witness was examined. He deposed that, so far as he could judge from external appearances, the boy had died from natural causes. "He was quite ready," he said, "to make a *post mortem* examination of the body, if the coroner directed him." Now mark the coroner's reply! "The magistrates were particular as regarded the expenses." There was therefore no internal examination of the body. The jury expressed themselves "perfectly satisfied" with the evidence adduced, and unhesitatingly returned a verdict of "Died from Natural Causes," and that no blame attached to any individual. Yet in January, 1845, when the guilty mother had added parricide and fratricide to her former crimes, the body of her child was exhumed, and the presence of arsenic detected in the stomach!

"Said we not truly that coroners' inquests were farces? Is it not the fact that they "shield off, *by their pretended performances*, that duty of searching inquiry which is the public's greatest safeguard?"

"What else but "a mockery, a delusion, and a snare," was the inquest on the body of James Dimond, that body remaining unopened? Had the child died by violence from without, no such examination might have been called *for*; but dying, as it did, if there were no need of an internal examination, then was there no need of an inquest; and no value in the coroner's inquiry; for how could the jury, no such examination being made, determine whether the child had died from natural or other causes? They rashly took upon themselves, without evidence, the responsibility of pronouncing a verdict of "Natural Death," and thereby incurred the further responsibility of two of the most revolting murders in the annals of crime."

THE PRELIMINARY BOARD.

Much misapprehension having arisen as to the character of this board, it may be as well to say that the examinations will have no express reference to medicine or surgery, but extend simply to the ordinary elements of a gentleman's education. It is not, as has been suggested to us, to be considered as a final arrangement, that only surgeons and physicians should preside at the board. When Sir James Graham spoke in the House of Commons on the proposal, he named the constituents as an unsettled point, using the words "I should say"—and much conflict of opinion yet appears to exist generally, whether the whole board should not be chosen by the Council of Health, or whether six General Practitioners should be added. We prefer the latter course.

COMMENTS ON THE AMENDED BILL.

To the Editor of the Medical Times.

Sir.—Being one of the few medical men, who think very favourably of the leading principles evinced in Sir James Graham's Amended Bill, "*for regulating the profession of Physic and Surgery,*" I am surprised to find words introduced there, which are, in my opinion, at variance with experience, justice, and good government; and I am not less surprised to observe that no notice has been taken of those words by the Editors of our Weekly Journals, or their Correspondents. I allude to the commencement of clause 38, wherein it is stated that "*none but persons registered as Physicians shall use the title of Doctor.*"

In the Bill I am referring to, there is no definition of the sense in which certain words are to be used; and the meaning of many terms is taken to be single, certain and unvariable, in direct opposition to truth and usage. This is particularly the case with the title of *Doctor*, which is neither limited nor limitable to the Medical Profession, but common to all the learned professions, and in no wise identical in signification with the word Physician; nor will any Act of Parliament make it so.

My idea of a Physician is old-fashioned, being derived from observation and experience during thirty or forty years, and were I to describe a real physician, I should say, "he is a Graduate or Doctor of Medicine of an University, practises in medical cases, rejecting operative surgery—prescribes for his patient, but supplies no medicines —takes no smaller fee than can be paid in golden coin of the realm, as the prompt reward for his time and professional talent." It is farcical to consider a man a physician, because he is a Doctor of Medicine, upon the authority of even a proper diploma, and takes the title or prefix of Doctor; yet this is the assumption carried through every part of the New Bill, and every speech made in the House of Commons referring to the subject, supports the erroneous idea.

The physician, however, as I have described him, is not the physician of the present day, and it is to be feared never will be in future, legislate as you will; examples have for years past been rife in our large towns, and even in the Metropolis, of physicians who take any fee they can get, trust patients in the expectation of receiving payment in the lump, contract to give attendance by the year, and do all other things, (save the very useful one of supplying proper medicines to their own patients,) that used to be done only by Members of the inferior grade of the Profession, and the avoidance of which was considered the physician's honourable distinction, much more than his title of Doctor. Above all, Sir, it deserves to be remarked, that there are in England, men who take the grade of Physicians, even Licentiates of the College of Physicians, and the appointed physicians of hospitals, both Metropolitan and Provincial, yet practice Surgery in all its branches; this has been the case with increasing prevalence, ever since the London College of Physicians ceased to require every candidate for its license to drop his College of Surgeons' Diploma; and in the progress of events, under the New Bill, what is to become of our Colleges of Surgeons, if the *registered* physician, besides obtaining *thereby* his legal title of Physician, engrosses also the title of Doctor, and practises as a consultant and operator in surgical cases, although he cannot be registered as, nor take the name of a surgeon! You will continually find men registering in the higher grade, but practising in the lower! I offer no crude nor improbable speculations, and assure you that although my name be concealed, in order to let my reasonings have neither more nor less than their due weight and influence, I have daily experience of a Hospital Physician, (being at the same time a Member, *not a Fellow* of the London College of Surgeons,) who profits what he can by the surgical practice of the hospital in which he holds his appointments, takes precedence of his seniors, the surgeons, in consultations on a surgical case, supports a sort of private surgical hospital of his own, and cultivates surgery, and even operative surgery, much more zealously than the branch of the profession in which he might honourably support his reputation and fill his exchequer. Is it for a physician of this class, that Sir James Graham would engross the title of Doctor? or is it to repress and degrade such a physician as I have described? I much fear that the Right Honourable mover of the New "Physic and Surgery Bill" has been misled to believe that those registered under that Bill will, in progress of time, be pure physicians, and not practising and operating surgeons, but there is nothing calculated to lead to such a result, however desirable it may be deemed. The more probable result is, that the registered physician, *the doctor par excellence*, will be the consulting surgeon, and that the College of Surgeons will be starved out as to members, rank, importance, and funds!

Writing *incognito*, I cannot be charged with presumption in stating my own views further on this subject, viz.: that to institute the title of Doctor in Surgery would be the only way to place this branch of the profession on its proper basis; there is the example of every other country in Europe, nay even of America, for the title. If it be too late now to discuss the point and to carry it into effect, we shall remain for many years to come behind all other civilized countries in this respect; for in all of them is the Doctor of Surgery recognized. It would be about as brilliant a proposal to legislate against travelling above ten miles an hour in the present day, as that none but those registered as Physicians shall take the title of Doctor; this is starting a slow coach indeed, and the Right Honourable the Home Secretary will know better than to engage in such a dull undertaking.

I humbly conceive, Sir, that the first object in legislating on medical affairs, is to fix *the minimum of education* that shall entitle a person to practice; and next to this, ranges the giving every reasonable encouragement to aspirants to take a more extended education than the minimum; both these objects are fully recognized in the Amended Bill; but the clause, that "*none but persons registered as Physicians shall take the title of Doctor*" is at variance with the latter of those objects, and gives a direct and severe check to the motives for taking an extended course of education. It is impossible that the Professors at the Scotch Universities, who are so fully cognizant of the fact that the Doctor's degree does not make the Physician, can be in favour of the clause I am considering. If the title of Doctor is to be kept in abeyance although properly obtained, until the individual is registered as a Physician, it is in fact the Council of Health that gives both titles at once, and renders them identical, and the University is deprived of its chartered right by a side wind; moreover the possession of the Doctor's *Diploma*, legally and properly obtained, is heavily taxed even by the Government, and unless it be *therein* provided that the title shall be kept in abeyance, it ought not to be, and cannot be so repressed. A majority of the legislature will never pass such a law, unless in ignorance of its injustice and injurious effects.

The leading surgeons and teachers of surgery in Dublin, who are generally Doctors of Medicine, and many of whom use the prefix accordingly, cannot be in favour of the clause I am condemning, unless they intend to register as Physicians, or consider that the title of Surgeon, ordinarily used as a prefix, is still equivalent to Doctor, of which it will be difficult to convince either the public or the profession in England. The objectionable clause cannot have originated in Scotland or Ireland; it has taken its rise, undoubtedly, from a source nearer the great centre of legislation; but the suggestion is not likely to be the less objectionable on that account.

What can the Senate of the University of London say to this obnoxious clause? They cannot fail to protest against it, whilst the *Curriculum* enjoined by this University is good, practical, and ample in all respects, its examination is deemed one of the very best in the empire, by all disinterested and enlightened members of the profession; the *Senators* know that a great majority of its medical Graduates are General Practitioners, who have no immediate view to becoming Physicians; but they are become Doctors of Medicine, and very honourably entitled to the designation, as evidencing superior education and the quickening ordeal of a searching examination voluntarily encountered. Sir James Graham ought to know how many of the graduates at this University are dull, stupid, ill-informed men, possessed of less than the average ordinary knowledge of the pure physician; and the information might aid him in coming to a right conclusion, whether all its future graduates should be required to register as physicians, *nolentes volentes*, (whether it suits their purpose or not, whether the public require them to practice, and will remunerate them in that capacity or not,) or present themselves under the discouragement of receiving no distinctive title for their *pains and penalties!*

As the Amended Bill refers to the whole empire, it will be quite allowable to select examples from any part of it; and we find in some portions of the kingdom, that surgeons of the highest grade, being at the same time Doctors of Medicine, now take the Doctorial title; and even respectable General Practitioners, where similarly qualified, do the same; this makes none of them physicians; but if the title have been legally and properly

obtained by graduation, they have a claim to it, and cannot be deprived of it, neither does the Amendment Bill contemplate depriving them of it, but will leave them in the same privileges they now respectively enjoy. Under the contemplated regulations for obtaining the title of Doctor of Medicine in future, there can be no proper motive for preventing those who attain the title, from using it; but on the contrary, students should rather be induced and encouraged to take the high course of education henceforth to be required, without reference to the grade in which they may subsequently register their names for practice. There ought to be no *Act of Parliament pressure* to make the well-educated register in the higher, in preference to the lower grade, as the former will inevitably be selected by individuals having the option, if the public want and desire them, and will remunerate them accordingly. We do not find hungry, half starved physicians, to be very valuable members of society or of the profession; indeed they are even at present often below, far below, the respectable surgeon-apothecary. It is incontrovertible, that the better the lower grade of the medical profession is educated, the fewer are required in the higher; this is as certain as that the effect follows its cause, and has been proved practically of late years in England, and it is a fact which supplies the powerful reason why the higher grades should not have the sole regulation of the education of the lower, whom it is their interest to depress for their own elevation. And now I beg to subscribe myself, Sir,

Your obedient servant,

Medico-Chirurgus.

May 26, 1845.

The writer of this communication is, we have reason to know, a very distinguished Provincial Surgeon.—Ed.

THE NEW INCORPORATION.

(To the Editor of the Medical Times.)

Sir,—Notwithstanding all the evils and difficulties with which we are surrounded, there is still one spot upon which medical men can rest a hope for salvation, and which hope will be most assuredly converted into a reality, if the Profession act with energy and unity of purpose. It is a God-send in prospective—I mean the *incorporation of General Practitioners*. Clause 14 in the present "Amended" Bill expressly provides for this new Incorporation. But I am bound to state that Sir James Graham is putting "the cart before the horse." He promises them a Charter, and upon the strength of that promise legislates upon this Charter, not legally defined—not granted—not in existence. The Charter should be first granted and presented to the House, in order that Parliament might know how to legislate upon it, and might have time to deliberate for that purpose. So long as the Charter is not granted, the Act must be premature, because it is recognising as yet a non-existing body, a non-existing Charter, and the members of Parliament may as well legislate for railways in the moon. If the Act first passes, Sir James Graham may then make the Charter what he pleases, at the private instigation of those whom he considers "most entitled to respect." *Some honourable member of the House should move for the immediate production of the Charter.* This is now rendered the more necessary, inasmuch as the Council of the College of Surgeons have come to the determination to oppose both Bill and Charter. The profession should secure this New Charter at once, before the Bill passes the Commons.

You, Sir, labour honestly and zealously for the Profession, but it is the fate of good hearts, when even combined with such clever heads as your own, sometimes to be deceived; not meaning any harm, they are sometimes off their guard, and do not always suspect the deeply lurking designs of others. The liberality which you evince to have all opinions freely canvassed, in order that your readers may arrive at truth, has occasioned your Journal to be supported by all parties, and given it a reputation as transcendant as its circulation is unequalled.

You say in your last leader "the Bill in its last improved stage is a mighty reformer of those family heritages—our snug and insolent Corporations. It puts them under thorough control. In the Council of Health it gives them a master that must do both them and us right. They get a ruler—we a court of appeal. * * * The Council will play the overseer to *them*. Parliament and our medical press will do the same for it. This is responsibility—a double, tangible, available responsibility." From this view of the case, I must with diffidence somewhat dissent. "The Council of Health" (save the two members to be sent by the new Incorporation of Practitioners) will be altogether made up of family *heritage-men*, or irresponsibles, or they will be only responsible to those irresponsibles of whom they will be the representatives. It will consist of those "*family heritage-men*," who have sacrificed the Profession and the public, for the sake of their monopolies; of those "*family-heritage* men," who, by their secret and evil advisings with the Home Secretary concocted both the Bill and the Charter of the College of Surgeons; of those "*family-heritage*" men who will be selected by the Crown on the Council of Health; of those "*family-heritage*" men who will constitute the Councils of the Colleges, and be selected by them, in the form of their condensed essence, as members of the Council of Health, and of those "*family-heritage*" men who, as the result of their secret whisperings, are unfortunately for the profession declared by Sir James Graham to be those "most entitled to respect." Nor will there be a sufficient number introduced into the "Council of Health" by the Corporation of Practitioners upon the elective principle, *to leaven the whole lump.*

The press, in my opinion, has never reformed a close Corporation so long as it has continued close; all that the press has done or has been able to do, has been to convert a close Corporation into an open one, in fact, to reconstruct it by means of fresh men begetting fresh measures, and this can only be effected by the *elective system*. By the latter means alone "family-heritage," power, money influence, and private favouritism (those death-dealing agencies to society) can be counteracted.

Nevertheless, my argument is, that if the present Bill, *per se*, is merely the external framework of Medical Reform without its vital parts, and if we find that all the evils in the Bill cannot at the present time be remedied, we had better bear the Bill for a while patiently, rather than lose sight of the "promised land"—*enfranchisement in a new Corporation.*

If we cannot properly infuse that spirit of moral life, the representative principle into the "Council of Health," and the at present existing Collegiate Councils, still, the suggestions of the Practitioners of Manchester are worthy of being pressed upon the House of Commons by the Committee of the "National Association," namely—that the New College should stand upon an equality of footing with the other Colleges—that in the initiatory examination intended as a portal for all branches of the Profession, the proposed New College should be represented by having the same number of members thereon as the Colleges of Physicians and Surgeons, and that the members of the New Incorporation, who hold the Diploma of the College of Surgeons, should be entitled to register as Surgeons; otherwise according to the showing of the Bill itself, a member incorporating himself with the new body, incurs a penalty, for the Amended Bill now provides that members of the College (not incorporated) may register as Surgeons.

Sir James Graham states that it has been urged by persons "who are entitled to the greatest respect," that the elective principle should be abandoned, and the power of nomination vested solely in the Crown. He, therefore, throws the Constitution of the "Council of Health" open to the consideration of the House—a House completely uninformed on medical polity:—The council-men "entitled to the greatest respect," full well knowing that whether the Council of health shall be constituted of representatives from the self-elect Collegiate Councils, or by Crown patronage, that they having the private ear of the Cabinet, and access to Court, will be the individuals chosen, and that their monopolies, privileges, and patronage will be perfectly safe.

The very fact of Sir James Graham granting the franchise to the "Royal College of General Practitioners in Medicine and Surgery," would compel him to grant a Supplementary Charter for the same purpose to the members of the Royal College of Surgeons, if the members were sufficiently and unremittingly strenuous in their endeavours.

My advice is to strive for both, and then we shall gain one, and should we succeed in both, no harm will be done; an honourable competition could exist between the Colleges as there is or ought to be between the various medical schools.

The members of the House of Commons require a great deal of information respecting medical matters. The *first* initiatory lesson given to them by Mr. Wakley on Medical Reform, on the 7th inst. should have been delivered years and years ago. There is still, with *your* powerful assistance, a bare chance of salvation left for the Profession. But we have a short time to act in and a great deal to do. It must be effected by *pressure from without.* I invoke the members to send in their petitions to the Home Office, and to the House of Commons. Is there a single individual, who, reading this, has not done so! Then he stands self-convicted; he has neither performed his duty to himself, to the Profession, or to his country.

Your obedient servant,

G. D. DERMOTT.

Charlotte-street School of Medicine.

[We have read Mr. Dermott's clever letter with very great attention. The only remark we will allow ourselves is, that the time for violent discussion on abstract preferences, and for displays of fervid antagonism on this and that practical arrangement, is gone by. As much good as they ever did, so much evil would they now do. Any promulgation of angry dissatisfaction now by any large section of the general body of medical men, will infallibly end in the minister's abandonment of it with disgust. The alternative is to carry the Bill with a high hand, and force it through the House with the majority he could undoubtedly command for it, and that is a step he will not take, out of deference to the feelings of those for whose satisfaction and benefit he can, at least, claim to have *intended* to legislate. Under these circumstances we have the solemn duty to perform of deciding whether it is better to take the responsibility of actively at once promoting its abandonment, or of accepting it as a whole, with the understanding, of using in a friendly spirit every influence we possess to modify such details as general consent may fix on as faulty. Mr. Dermott, we are glad to see, prefers the latter course: we are certain that nine-tenths of the Profession will share his opinion; what then becomes the immediate duty enforced on us? Why, obviously, first to depose every feeling of partizanship and anger in reference to medical topics, and, still more, any personal prejudices arising from general politics, that may prevent our meeting the Minister in the most cordial and friendly spirit; and, secondly, while acknowledging thankfully the improvements he has advanced to, and promising him further our best support, to let Parliament and the country know, that if he has at the suggestion of the Profession made grave and numerous alterations on his former proposals, he has for his proud justification to show the approval, support, and gratitude of the learned body for whom they were made. This footing of friendliness and mutual cordiality being thus established, we are perfectly certain that if Sir James Graham will not introduce for us any further vast innovation—and that *now* we can hardly ask—he will, at least, correct for us the minor *defects* which we may point out to him, and will carry out the *details* of his proposals in that liberal and equitable spirit, required by his own reputation, and so irresistibly recommended to him by the dispassionate authority of political foes and friends, all here uniting and co-operating with him for this settlement in a cordial spirit of amity and good-feeling.—Ed.]

NEW EFFORTS AT DISSENSION.

[The following letter is from Mr. Hillier, of Gower-street, a gentleman who, as "the successor to Mr. Pennington's huge practice"—we quote the *Lancet*—was but too gladly chosen by Mr. Wakley to fill the chair at the meetings he endeavoured to raise against the National Association. Mr. Hillier, however, entertaining the sentiments customary to gentlemen who have borne a commission in the service of our country, it was easy to foresee that the *rapport* could not last. As Mr. Hillier joined the movement in perfect ignorance of his associate *personally*, so the moment he had become acquainted with him personally, that moment did he close the connection. We consider the present letter to offer important testimony from authority the most unquestionable.—Ed.]

Sir,—On Saturday last, in compliance with the following request, I attended a preliminary meeting of the profession at the Freemasons' Tavern, Great Queen Street:—

"The attendance of Mr. Hillier is earnestly and particularly requested this (Saturday) evening, May 24th, at the Freemasons' Tavern, Great Queen Street, at half-past seven, to join a preliminary meeting for the purpose of considering the arrangements for an aggregate meeting of the medical profession, at which Mr. Guthrie *has* consented to preside."

I found a number of gentlemen assembled, and Mr. Bottomley, of Croydon, took the chair; upon my enquiring of the chairman the specific objects of the meeting, I was given to understand by Mr. Wakley, who made a long speech upon the subject, they were three-fold, viz.:—

1st. "To obtain, if possible, for the members of the Royal College of Surgeons, their enfranchisement in their own college."

2d. "To oppose parts of the Bill as amended by the Committee for regulating the profession of Physic and Surgery;" and

3d. "To oppose the grant of a Charter of Incorporation to the National Association of General Practitioners."

I stated that the two latter objects were incompatible with the course I had advised and adopted, at the last general meeting of the profession, held at the Hanover-square Rooms, but I was ready to go to any lengths to obtain the first.

Before any resolution was proposed on the subject, I left the room and was followed by several gentlemen, who with myself, could but regret that our profession should again be subjected to useless *agitation*, injurious to us as a body in the eyes of the public, and likely to frustrate the intentions of a minister, who is at present kindly disposed towards us.

Let us obtain *some* legislative measure for the regulation of our profession, and if errors become apparent in carrying out its provisions, surely we can get them amended; and as we cannot get the desired enfranchisement in our own College, because the "Minister refuses to advise the Crown either to alter or rescind the charter which he gave the Council of the College, and because the Legislature, (which generally acts in accordance with the Minister) will not lend its ear to any prayer having for its object the revision or alteration of that charter," let us receive a charter of incorporation of General Practitioners, independent of the Royal College of Surgeons, but on equal terms with all the other Colleges, and the General Practitioners will rise in public estimation, whilst the dishonest proceedings of the Council of the College of Surgeons in carrying out the charter, will secure to them for ever, the scorn and contempt of all honourable men, but more particularly of its own members.

I am, Sir,
Your's obediently,
H. B. C. HILLIER.

85, Gower Street, Bedford Square.

RESULTS OF THE NEW BILL.

To the Editor of the "Medical Times."

Sir,—I shall feel particularly obliged if you will inform me what steps are necessary, or which will be the most advisable plan to adopt, to obtain a diploma in as *speedy* and *economical* a way as possible. I have been practising without one, in comfortable practice, for some years, but find the law about being altered, and feel doubtful, whether, if I delay, the new system may not be too stringent for me. As a matter of course, your cognizance of all matters connected with medical practice, is of that nature, that I feel persuaded you can give me all the information I require. By so doing (and in confidence) you will oblige a constant reader of your journal.

I am, Sir,
Yours respectfully,
JOHN STOREY.

Manchester, May 24th, 1845.

[Our very *simple* correspondent, Mr. Storey, desires us to address to him our *private* note to the care of——"*Surgeon*," in Chorlton-upon-Medlock—whose name we do not deem it necessary to give, although he is very probably the real author of the letter of Mr. Storey. There are, doubtless, many persons in practice under *false* colours, like our correspondent: the new Bill will unearth them, and while thus effecting the good of not making us responsible for the faults of men really not of our order, will secure that portion of the public, who will not be treated by an uneducated quack if they know it. It is perfectly absurd, for the present, to expect that the Apothecaries' Society will commence any more actions against men who profess to practice as "surgeons," though using the privileges of apothecaries. Now, that the Bill is in that critical instant when we must actually accept *it* at once, or do without an enactment for we know not how many years,—it does behove us to try all we can to get whatever benefits it offers us, although the effort oblige us to forego many a cherished wish and preference.—Ed.]

PROGRESS OF ENGLISH, ITALIAN, AND AMERICAN MEDICAL SCIENCE.

[The following are the principal articles of interest to our readers in one number of the *London Medical Gazette*.]

The floating corpuscles of the blood.—Dr. Owen Rees, in the Gulstonian Lectures, thus describes the floating corpuscle. This body has been very differently described by physiologists; some having considered it as composed of solid matter—in fact, that it is a soft solid—while others consider it to possess a vesicular structure. There are considerable and important differences of opinion, however, existing even among those who agree in believing the corpuscle to be a vesicle, some regarding it as made up of a white membrane, containing a fluid of a red colour, while others believe that the vesicle is red, and the contained liquor of a pale tint. The existence of a nucleus in the corpuscle of the human blood is also denied by many; and the exact situation it occupies again divides the opinions of those who believe in its presence. In considering these conflicting opinions, it might at first appear a matter of extreme difficulty to resolve any part of a question depending so much on microscopical evidence; but though there are still many difficulties to contend with in the demonstration of a nucleus, we have fortunately obtained a means of determining pretty certainly two of the points in question—first, that the corpuscles possess a vesicular structure, and secondly, that the fluid contained within the corpuscle is red, and the containing membrane white. If fresh blood be mixed with a watery solution of sugar, salt, or indeed any soluble matter which will not act chemically on the blood, we shall find, on microscopical examination, that certain physical effects are produced on the corpuscles, varying according to the specific gravity of the solution with which the blood has been mixed. Now, presuming the blood corpuscle to be a vesicle or closed membrane containing a liquid, the specific gravity of this must be the same as that of the fluid in which the corpuscle floats, for such is the necessary consequence of stasis; and if, by altering the specific gravity of the fluid suspending the corpuscle, we alter the condition of the vesicle itself, by changing the proportion of its contents, in accordance with the laws governing endosmodic action, it is no longer possible to resist the conclusion that the blood corpuscle is truly a vesicle or bladder containing fluid. Experiment has shown that such effects really occur; thus if we mix freshly-drawn blood with a solution of a specific gravity higher than that of the liquor sanguinis, we immediately observe the form of the corpuscles to alter—they become flaccid and empty, owing to the liquid of high specific gravity having drawn from the vesicle a larger proportion of fluid than it supplied to it, in accordance with the law of endosmosis. If we reverse this experiment, by mixing with the blood a solution of lower specific gravity than that of the liquor sanguinis, a contrary effect is immediately produced, the corpuscles becoming distended and rounded in a very marked degree; more fluid in this case entering the corpuscle, while but little will pass out. If to these corpuscles, so altered by the action of solutions, we now again apply these tests, but on this occasion add the solution of low specific gravity to the collapsed corpuscles, and that of high specific gravity to those distended, we shall find that we are enabled to return each specimen to its former condition, or nearly so. It has been found by careful experiment that in order to collapse the corpuscles a solution of sp. gr. 1060 is required; but this acts slowly in some cases, and to produce the effect decidedly a solution of 1070, or more, should be employed. Solutions cease to distend the corpuscles when of sp. gr. 1050 to 55, and to distend them well a solution of 1015 or 10 is desirable. Now the specific gravity of the blood is about 1057 to 60; and as the corpuscles remain unaltered by solutions of from 1050 to 1060, we may conclude that the average specific gravity of liquor sanguinis lies somewhere between those two points, which it is a matter of some interest to have ascertained, as it proves that the fibrin of the blood is dissolved, and not suspended in the liquor sanguinis. For were the latter the case, the corpuscle would be rapidly collapsed by solutions of 1050, inasmuch as the serum suspending the fibrin could only have a specific gravity of 1029 to 30, and the corpuscle would of necessity contain a fluid of no higher specific gravity than this. The remaining question, as to the colour of the vesicle and its contents, is thus disposed of. It has been already shewn that liquids of high sp. grav. are capable of drawing out a large proportion of the contents of the corpuscles, and so rendering them flaccid, while liquids of a low sp. grav. draw out but little of their contents, supplying to them a larger portion of fluid than they draw from within, and thus producing distension. Now this being the case, it is evident that if we obtain some means of ascertaining the colour of the fluid floating round these corpuscles, both in the distended and flaccid state, we shall (presuming the contained liquor to be of a red colour) be able to detect in one case a deep red tinting, and, in the other, a very light stain, only communicated to the fluids in which the corpuscles float. These experiments, repeated on a large scale, gave the same result in a very striking manner. The colour of the vesicle itself was ascertained by destroying it, by adding pure water, which distended and ruptured it. The experiment was conducted as follows:—A quantity of corpuscles was allowed to subside from serum into which they had been introduced, by breaking up in it a portion of crassamentum, and then pouring it off, while containing corpuscles in suspension, leaving behind the coarser particles of broken crassamentum, which were allowed time to sink to the bottom. This mixture was set to stand during several hours, at the expiration of which time, the corpuscles had collected at the bottom of the vessel. The supernatant clear serum was next poured off, as nearly as could be effected without disturbing the deposit. This having been done, the mass of corpuscles was thrown into distilled water, and this mixture set aside for twelve hours. The anticipated result was now obtained: the water had burst the corpuscles by rapid endosmose, the burst envelopes had subsided, and were collected in a white stratum as a precipitate, while the supernatant liquid held the red colouring matter in solution. The deposit is made up of three kinds of bodies:—

1st, substances quite such as might be expected to result from the bursting of envelopes, having the appearance of shreds of membrane, some corrugated, others flattened out; 2dly, white bodies, somewhat resembling the blood-corpuscles, thin at their edges; and about two-thirds the diameter of the corpuscles; 3dly, granules, probably due, in part, to serum, and in some measure, to partial disintegration of the nuclei.

TETANUS.—Dr. Blackmore narrates a case of idiopathic tetanus, occurring in a female, twenty-two years of age, which he treated, but unsuccessfully, by bleeding, calomel and opium, opium, and warm baths. The influence of the mineral became evident before death, which occurred in the bath. On examining the body after death, the dura mater at the upper part of the spinal cord, was found to be very vascular, and coated with greenish fibrine.

FISTULA IN ANO.—Mr. Lomas treats fistula in ano by the application of a ligature in the following manner. He employs a fine metallic wire of silver or platinum. Having passed a probe director (one of Sir Benjamin Brodie's) along the fistula, and through its internal orifice, its point, being very flexible, is readily directed downwards and out at the anus by the finger previously introduced within the rectum; the structures to be divided are now upon the instrument, and, as it were, everted. The wire is then passed along the groove of the director, and the ends are twisted together until a very moderate compression is exerted upon the enclosed parts. It promotes the personal comfort of the patient, to leave the twisted ends rather long, and to fix them on the sacrum with a cross slip of adhesive plaster. This trifling arrangement allows the buttocks to lie perfectly apposed, and the patient is free from the disagreeable sensation of an interposed body or rough point, and visits the closet more comfortably. All that remains to be done is, to twist up the ligature as it becomes slack, and in a week, or a little more, it is free. The patient should be confined to the sofa for a day or two after the operation.

THE SEROUS MEMBRANES.—Dr. Willis is disposed to view the serous membranes as internal substitutes for the external common integument, and the fluid that perpetually bedews the surface of these membranes as having the same effect as the perspiration, the purpose of the cutaneous exhalation and of the serous exudation being identical; viz., the preparation of the conditions by which the fluid shed from the capillary arteries finds its way, in principal part, back into the circulation. He had previously shewn the influence which the extensive system of sudoriparous glands exerts in this direction, by dissipating so much of the watery element of the blood. With regard to the serous membranes a different arrangement was required. The exudation from them cannot pass off in the form of vapour into the atmosphere; it is, therefore, collected and carried away by a set of vessels especially provided for the purpose, being imbibed or taken up by them in virtue of a general physical law. These vessels are the absorbents, which, as complementary to the veins, are in particular relation with the watery parts of the plasma, or liquor sanguinis, which passes through the parietes of the capillary arteries at every point, charged with the elements of nutrition appropriate to all the tissues composing the body. These tissues select what they require from the plasma that bathes them, and, at the same time, doubtlessly set free certain effete matters—carbon in the form of carbonic acid, hydrogen in the shape of water and bile, and azote in urea, all of which, dissolved in the lymph, are taken up by the absorbents, and, being thrown into the general current of the circulation, are by and by sent for elimination by organs especially destined for the purpose,—the lungs, the liver, and the kidney. The walls of the absorbent vessels have an affinity for the watery fluid with which they are bathed, in the same way as the empty intestine of an animal placed in water has an affinity for that fluid, and becomes distended with it. Abstracting watery fluid, they have the effect of rendering the current of blood which is returning to the heart more dense than that which is quitting it, and so secure the perfect drainage of the tissues at large by the medium of capillary veins; for the lymphatics themselves do not appear in any case to penetrate the substance of organs, and are nowhere of dimensions so minute as to make them invisible to the naked eye. The watery fluid appropriated by the absorbents is not poured into the veins in the vicinity of the parts and organs where it is collected: this would have had the effect of attenuating the returning current, and undoing all that had been done; it is only restored to the blood as the common torrent is entering the heart, at the nearest eligible point, it may be said, to that organ, from which it is immediately sent to undergo exposure in the lungs, and besides the special purgation which it then receives, it loses as much water as will give the blood of the pulmonic veins a somewhat greater density than that of the pulmonic artery, and so effect the drainage of the delicate tissue of these organs; this is, in fact, probably the end of the pulmonary exhalation which, as is known, amounts to several grains per minute—to several ounces in the course of twenty-four hours.

DISSECTING ANEURISM OF THE THORACIC AORTA.—A woman, 50 years of age, having died suddenly in the South Dublin Union, after suffering for a short time from excruciating pain in the epigastric region; her body was examined after death. The pericardium, which was healthy, contained about four ounces of serum tinged with blood and some coagula. At the origin of the great vessels there was a large and firm mass of coagulated blood, bound down by the thin layer of serous membrane which passes up from the heart along the vessels, to be reflected on the fibrous layer of the pericardium. The left ventricle was dilated and hypertrophied, the semilunar valves atrophied and thinned. The aorta, in the situation of the attachment of the valves, was healthy; but about an inch from this situation, there was discovered a laceration extending transversely, and with edges as well defined as if cut with a scalpel; it penetrated the internal and middle coats of the artery, but left the external one quite whole; it was one inch and three-eighths in extent, and from it a probe could be passed downwards, between the external and middle coats, as far as to a level with the upper border of the semilunar valves; but farther than this, *i. e.* behind the sinuses of Morgagni, it could not be passed. The orifice of this slit was partially closed by a coagulum of pale fibrine, and on tracing this up it was found to lie between the external and middle coats of the vessel, but did not extend far, and was not attached. A probe was then passed upwards, which advanced as far on the right side as to the division of the innominata, and for about half an inch along the course of the left subclavian and carotid arteries, to which extent the middle tunic of these vessels was separated from the outer one; but the space was not occupied by a coagulum; it appeared as if the separation had been the effect of a violent pumping of blood between the coats of the vessel, which had afterwards burst into some other situation, leaving this space empty towards the laceration. On proceeding with the dissection, the opening in the cellular coat through which the blood escaped, was discovered; it was round, about the size of a fourpenny-piece, and was filled with a dark coagulum, which extended downwards, closely embracing the aorta, and separating this vessel from the pulmonary artery at the exact place where, in health, they lie in apposition. In this situation the coagulum exercised a considerable compression on the pulmonary artery, by which the vessel was much flattened. The coagulum lay beneath all that portion of the reflected layer of pericardium, extending from the zone tendinese of the right and left ventricles to where it is reflected on the under surface of the fibrous layer of the membrane. The serous membrane was perfectly whole, except at a small point corresponding to the junction of the right ventricle with the left auricle, where there was a small aperture through which the small quantity of blood in the bag of the pericardium had evidently escaped. The clot was hard and solid, and was fixed in its position, from its being completely entangled in the cellular tissue lying between the serous membrane and the outer coat of the arteries, and between these two vessels at the point where the pulmonary artery passes anterior to the aorta; in this spot the coagulum was thicker than in any other. In other respects the aorta was extensively diseased, being thickly coated from the commencement of its transverse portion, all along its descending course, with bony plates and atheromatous deposits. Indeed, the only part of the artery which appeared free from this disease was the very situation where the laceration took place; for immediately to the left of the opening there was another large osseous deposit. On comparing the middle and internal coats of the artery, at the seat of rupture, with other parts, they were found to possess scarcely half the thickness, and were much more friable, though the vessel did not present, in any part, traces of acute inflammation. Towards the commencement of the arch the vessel was somewhat dilated, but not to a greater extent than is ordinarly observed in individuals of her age. The mouth of the innominata was filled with a dark and firm clot, which extended for some distance along this vessel and its two divisions, and appeared to have been produced by the mechanical pressure exercised on it by the clotted blood which lay between its outer and middle coats. The lungs and liver were greatly engorged, no doubt the result of the mechanical pressure exercised on the veins leading from them, and of the almost complete obliteration of the cavities of the auricles.

ATROPHY OF THE HEART.—*Inspection.*—Cardiac movements, imperceptible to sight, and often to touch.—*Auscultation*; sounds of the heart distant and feeble.—*Percussion*; In consequence of the diminished organ being overlapped by lung, the præcordial region yields almost as clear a sound as the opposite side. The history of the case, its supervening upon chronic and debilitating affections, and the permanently small thready character of the pulse, will assist the diagnosis. Constant and unremitting sedentary occupation, with a deficiency of pure air, proves a not unfrequent source of atrophy of the heart.

DISPLACEMENT OF THE HEART.—Dr. Durrant in the *Provincial Medical Journal*, says, the diseases within the thorax causing unnatural deviation of the heart to either side, are, copious pleuritic effusion; hæmorrhage into that cavity from external violence; pneumo-thorax; empyema, with liquid effusion; extensive pulmonary emphysema of one lung; tumour, either of the mediastinum or lung; aortic aneurism; to which may be added, the rapid absorption of a pleuritic effusion, the heart being drawn to the affected side (Stokes); and, lastly, universal consolidation and contraction of one lung, with hypertrophy of the opposite (Hope). Depression of the heart may be caused by extensive emphysema of both lungs; tumours within the chest; aneurism of the arch of the aorta; and, to a certain extent, by gravitation, from great enlargement of the organ itself. The heart may be pushed upwards by enlargement of the liver, ascites, abdominal tumours, and by a flatulent distension of the stomach. In rare instances, a contracted and atrophied lung from tubercle, will induce elevation of this organ.—In a case of rheumatism, admitted into the Ipswich Hospital a short time since, the heart was found to be considerably displaced, both upwards and backwards, by a stomach enormously distended with flatulence. The apex of the heart could neither be seen nor felt; the situation of the base was higher than natural, and the sounds very indistinct; the entire præcordial region, and beneath the sternum from between the third and fourth ribs downwards, afforded a loudly tympanitic sonoriety. On careful percussion, the shape of the distended viscus could be traced with tolerable accuracy. Under the use of purgatives, the phenomena of the heart's action assumed their natural position.—The only correct guide to the formation of an accurate diagnosis, in reference to the extent and manner in which the heart has undergone displacement, is an acquaintance with its normal position within the chest, more particularly the situation of its apex, and that of the sigmoid valves: over the latter, it will be recollected that the second sound obtains its maximum. These points decided, the amount of deviation from the

natural position which the organ has undergone, may generally be ascertained with considerable precision.

Hypertrophy of the heart.—Dr. Durrant, in the *Provincial Medical Journal*, gives the following physical signs of hypertrophy of the heart:—*Inspection.*—Impulse of the heart visibly increased, forcibly raising the hand or stethoscope; the apex of the organ is seen and felt pulsating lower than natural, often between the seventh and eighth ribs. In extreme cases, the præcordial region is rendered prominent. *Auscultation.*—Force of the heart's action permanently increased, and heaving, raising the hand of the observer, receding abruptly again with a shock, constituting the back stroke, or diastolic impulse of Dr. Hope. This phenomenon is caused by the sudden refilling of the ventricles. The sounds of the heart are deadened and obscure; the first sound is prolonged, dull, and limited to the præcordial space; the second sound very feeble and indistinct; most audible over the situation of the sigmoid valves. In consequence of the prolongation of the first sound, the period, prior to the succeeding rhythm, is much shortened. *Percussion.*—Increased dulness, both transversely and vertically. In concentric hypertrophy with contraction, the phenomena are similar to the above, but more immediately confined to the præcordial region. In this variety, the impulse is less, the sounds more feeble and limited, while percussion gives the sensation of greater resistance to the finger, without increasing loss of sonoriety.

Effects of Drinking Cold Water.—Dimness of sight; syncope; spasms of the chest and stomach, staggering, imperceptible pulse, and laborious respiration. Sudden death, says Thomson, has often been observed to be produced by drinking large draughts of cold water. Indeed, this effect of cold upon those who have suffered much previous heat, thirst, and fatigue, has long been known. Quintus Curtius, in particular, gives a very interesting account of the fatal effects which the army of Alexander the Great experienced on reaching the banks of the river Oxus, after a fatiguing march through the sterile and burning sands of the desert. Those who indulged in drinking freely of the stream died immediately; and Alexander, the historian remarks, lost more men by this means than he ever lost in battle. Numerous well-authenticated instances of sudden death from the same cause are to be found in the records of medicine.

Purulent catarrh of the biliary ducts.—At a meeting of the Pathological Society of Dublin, Dr. Oliffe, of Paris, presented a papier maché cast of a liver affected with a peculiar disease, which he has denominated purulent catarrh of the biliary ducts. The patient was a gentleman, 46 years of age, who had previously suffered from jungle fever in Bengal, and afterwards with intermittent fever and jaundice. He visited France in November last, and towards the middle of December was seized with a febrile paroxysm, which was succeeded by complete loss of appetite and general debility. Dr. Oliffe saw him on the 1st of January. He then presented the following symptoms:—The facies was pale and presented a slight icteric hue; the sclerotic membranes were faintly tinged with yellow; no appetite; the tongue was covered with a thick yellowish fur; the urine saffron coloured, evidently by the presence of bile; the fæces were normal, both in colour and consistence, and did not present the white colour which distinguishes the alvine excretions of jaundiced individuals. There was no pain, and the patient complained of his continued loss of appetite. The hepatic region offered no prominence; on percussion Dr. Oliffe found that it extended abnormally into the thorax, but its inferior border did not pass the last ribs. The remaining abdominal viscera appeared to be sound and no abnormal phenomena were apparent in the lungs, nor in the heart. The febrile paroxysms which were renewed at irregular periods, were similar, in every respect, to those of intermittent fever. Calomel and colocynth were prescribed, and friction with the unghydrargyri on the hepatic region. The fever, which had been previously of irregular type, now became tertian, and was at first much relieved by the sulphate of quinine. But the improvement was of short duration; the fever soon returned, it became continuous, with evening exacerbations; the tongue dried up, the general debility was considerable; and the patient rapidly lost bulk. During this period, as well as throughout the malady, there was no pain whatever in the hepatic region. Effusion afterwards took place to a slight extent into the cavity of the peritoneum, and the patient was ultimately carried off by diarrhœa. On examination of the abdomen, thirty-eight hours after death, the stomach was distended with gas, and the left lobe of the liver was rather prominent in the epigastrium. The peritoneum contained about a quart of citrine serum. The liver was the subject of special observation. Its inferior margin did not extend beyond the last false rib; but superiorly it was enlarged; it pushed up the diaphragm considerably into the thorax, and extended to the level of the fourth rib. A finger introduced into the *sulcus transversus*, produced a rupture of the hepatic tissue, from which issued about ℥vj. of yellow creamy pus. In the middle of the superior surface of the right lobe, was a circular eminence, of a dark brown colour, studded with black spots. On incising this tumour, a quantity of pus oozed through numerous orifices; and the same occurred after incisions made in different parts of the organ. A female catheter introduced into several of these orifices, penetrated into ramified canals, which were soon judged to be the biliary ducts. In order to form an accurate knowledge of the source whence the pus was furnished, the liver was placed on its convex surface, and commencing at their origin, the ducts were examined in their divisions; they were much dilated, and *all* contained pus coloured with bile. Their mucous membrane was softened, of a black colour; the gall-bladder contained a small quantity of dark-coloured bile, in which were found four small biliary calculi; the mucous membrane of the gall-bladder was red, injected, and rather softened; the vena portæ and the hepatic veins were next examined, and were found to be perfectly sound; the tissue of the liver was likewise sound and contained no abscess, nor any purulent infiltration; the spleen was normal; there was no pathological alteration in the stomach nor intestinal canal; the heart was rather large; the pulmonary parenchyma remarkably sound. The other viscera presented nothing worthy of observation.

Encephaloid Carcinoma on the Brain.—Dr. Cowan has published in the *Provincial Medical Journal*, two cases of encephaloid carcinoma of the brain, from which he draws the conclusions that where the local and general symptoms justify the diagnosis of an organic affection of the brain, and when these are accompanied with remittent or intermittent pains of a neuralgic character, gradual emaciation, and cachectic appearance, we may with high probability, infer the existence of malignant disease. The first patient was a lady thirty-five years of age, suffering from hemicrania after miscarriage and flooding, attended by all the well known general and physical indications of anæmia, the paroxysms of pain, occupying the left side of the head and face, recurring at short and irregular intervals, preceded by a distressing whizzing, pulsatory noise in the right ear, and, when at their height, associated with severe lancinating pains through the right arm and leg. The tinnitus which was not accompanied by deafness, continued until death, and proved rebellious to every form of treatment. The pains in the right arm and leg became gradually less severe, and ceased after the first fortnight. It was subsequently noticed, that during the fit, and sometimes immediately before, the right arm was relaxed and motionless, recovering its ordinary power when the pain subsided. It was not clearly ascertained whether the sensibility was disturbed, nor did the right leg participate in the temporary motor paralysis. Vision was also subject, during the last three or four weeks, to singular alterations. Sudden darkness and confusion of sight, particularly of the left eye, amounting at times to blindness, would accompany the seizures, and occasionally continue, but in a less degree for several hours. The head-ache gradually extended to the right side, was less and less intense, and paroxysmal, and often fixed in the occiput and orbits. It subsequently amounted to a general uneasy feeling, rather than to pain; and the attacks assumed more of an epileptic character, as indicated by sudden stillness, stupor, and at times insensibility, with occasional rigid extension of the left leg and arm. Mental and muscular effort uniformly tended to bring them on. The patient preferred the horizontal posture, was disinclined to move, and seemed always comfortable when dozing or asleep. Her nights were, with scarcely an exception, undisturbed. The digestive functions were not affected; the emaciation was slow, though progressive; and the complexion assumed more of a sallow tint. She died comatose, the epilepilepti form attacks having ceased for nearly a week previously.—*Post-mortem*, twenty hours after death. Neither the bones nor membranes presented any morbid appearance. The brain itself looked externally healthy, except the convolutions of the inferior portions of the middle lobe of the right hemisphere, resting on the temporal bone; these were smoother than elsewhere, and soft and elastic to the touch. The greater portion of the corresponding medullary matter was converted into a red, pulpy and vascular substance, with numerous hemorrhagic points, and a black coagulum, as large as a hazel nut, in the upper portion, breaking its way through into the ventricle. The latter contained a drachm of bloody fluid. Neither the membranes nor the grey matter were implicated. A thin layer of softened brain separated the diseased from the healthy portions.—The centre of the posterior lobe of the left side presented precisely similar appearances. The diseased structure had also penetrated into the ventricle, and extended to the posterior surface of the optic thalamus. In the centre of the right anterior lobe, a distinct portion, about the size of a nutmeg, and in an earlier stage of similar transformation, was very clearly and beautifully seen, surrounded by healthy brain. The nature of the morbid structure was, in every respect, that described under the term of encephaloid carcinoma. In the second case, also that of a female, the disease first showed itself in the form of severe headaches, which gradually subsided after getting up, and the patient was also sensible of peculiar uneasy, quivering, fidgetty sensations in the legs, particularly the left; these, at times, forced her to continual movements for relief. She felt as if she could not sit still. This occurred in March, 1844. In May, she complained of partial numbness in the left cheek, and was observed to stagger in her walking; deviating from a straight line, and to the left, as if she had lost the directing power. It was compared by those about her to the effect of slight intoxication. The headaches became more intense, at times agonising, with distressing vomiting, and on the 8th of June, when preparing to ride out, she was seized with præcordial pain and palpitation, violent congestion of the head and face, embarassed speech, and mental confusion. The day following, the power of utterance was impaired, the loss of sensation in the cheek complete, and she was deaf in the left ear. For these symptoms she was bled, leeched, and salivated, and blisters and a seton applied. For a month subsequently the headaches materially diminished, but the excitement, restlessness, distressing feelings, uncertain movements, emaciation, and general lassitude, gradually increased. In August, deglutition was rather difficult, and strabismus, principally of the left eye, was noticed, with partial loss of vision on the same side. The headaches returned with still greater intensity, and were referred to the left parietal and and occipital regions. The irregularity in her voluntary movements gradually affected the arms as well as the legs. There was no paralysis of movement or sensation to the last, nor was one side more distinctly implicated than the other; but the controlling, the co-ordinating power of the muscular system, appeared abolished, or nearly so. She died February 18, 1845. Post-mortem, thirty-six hours after death.—Extreme emaciation; scalp dry, thin, and bloodless; skull of average thickness and density; it separated easily from the dura-matter, and the inner table was deeply

furrowed, and of a rather porous structure. All the membranes presented great venous turgescence, with soft dark coagula in the larger trunks; about an ounce of pink-coloured serum drained from different surfaces to the base; a small quantity of opalescent fluid was lodged under the arachnoid in the sulci; the membranes were of healthy firmness and transparency; no bony irregularities. The cerebral convolutions were deep and numerous; the grey matter very distinct, and the brain throughout vascular, particularly the cerebellum. At the base there was a dark-red, spongy and highly vascular substance, presenting all the wellknown charrcters of encephaloid carcinoma, incorporated with the anterior extremity of the left lobe of the cerebellum, of which it seemed a prolongation, passing forward in inseparable connection with the pons, and following the emerging fibres of the corresponding crus cerebri; it terminated about an inch further, without penetrating the ventricle, in the moduallary substance of the middle lobe; where it presented a more brokendown and disorganised appearance. It originated about a quarter of an inch posterior to the pyramidal fissure, involved the whole thickness of this portion of the cerebellum, and nearly an inch in width, penetrating irregularly into the substance of the pons and left crus, from which, as well as from the cerebellum, it seemed to grow and sprout. The pia mater only covered it at a short distance from the cerebellum, and the general surface was irregular and shaggy. The line of separation between the diseased and healthy structures was indistinct, but no membrane intervened, nor was there more than very slight softening of the surrounding cerebral pulp. The medulla oblongata, and the pons, were pushed to the right, forming an obtuse angle with the spinal marrow, and the left pyramidal and olivary bodies appeared stretched and slightly softened. The left pneumogastric nerve was thinner and more filamentous than its fellow, and the seventh, fifth, fourth, and sixth nerves, passed over and partially through the morbid growth, and at their exit from the skull were vascular and soft. At a precisely corresponding point of the right side, in the centre of the white fibres, as they leave the cerebellum to pass over the pons, a small nucleus of encephaloid matter, about the size of a large pea, was imbedded, as if formed at the expense and not by the displacement of the surrounding tissue. The morbid growth on the left side, was therefore limited by the tentorium superiorly, by the petrous portion of the temporal bone anteriorly, and could only increase in bulk by pressing the mesocephale upwards and to the right.

TRANSACTIONS OF LEARNED SOCIETIES.

Royal Medico-Botanical Society. Feb. 18, 1845. Dr. Cooke in the chair.

A communication from Lieut. Hardy, R. N., on the polecat tree was read. This shrub is indigenous on the banks of the Missouri, and is supposed by Lieut. Hardy to be a species of mimosa. It derives its name from its emitting an unpleasant odour when touched. The bark possesses the singular property of removing, when masticated, the unpleasant tenderness and sponginess of the gums attendant on scurvy, the characteristic of which is their bleeding on the slightest pressure. The specimen of the bark in his possession was presented to him, when in Mexico, by an American hunter, from whom he obtained a knowledge of its medicinal virtues. During his residence in the province of Sonora, he frequently witnessed the beneficial effects resulting from its use, seeing that to such degree are the people—both men and women—affected by the local disease, that it is no uncommon thing, on awaking in the morning, to find the mouth full of coagulated blood, and in some instances even the pillow completely stained by the hæmorrhage. In these extreme cases, there is great debility, caused by the long continuance of the disease, notwithstanding which the benefit produced by the bark was only the more apparent and convincing, and, he adds, the more certain, for in no instance did he ever know it fail of the desired effect. In flavour, when fresh, the bark is not unlike the radix pyrethri, though very bitter, and like it, it is chewed for a short time.

GOSSIP AND NEWS OF THE WEEK

The following gentlemen were admitted Members of the Royal College of Surgeons, on Friday, May 23rd, 1845:—R. Lumb, W. C. Hood, J. C. Martin, B. S. Hopewell, M. A. Savage, J. A. Savage, J. A. Walcott, T. B. Eames, and H. J. Fotherby.

The following gentlemen were admitted Members of the Apothecaries Hall on Thursday, May 22nd, 1845:—John Thomas Newberry, Rowland Flockton, Edm. Warlams, Geo. Royde, and Josiah Roope.

Dr. Babington was, on Tuesday evening last, elected one of the vice-presidents of the Royal Medical and Chirurgical Society, in the room of Dr. Theodore Gordon, deceased. The meeting, which was a special one, was very thinly attended. When will the general practitioners belonging to the society bestir themselves to ensure the election to office of one of themselves. They are numerous enough, and of sufficient influence to demand that some of the honours of the society be bestowed among them, and there are certainly many gentlemen in general practice, fellows of the society, equally as deserving of such distinction as those who now obtain it. Let them shew their strength, and they will succeed. The National Association of General Practitioners has set them a good example.

Assistant Surgeons in the American Navy.—By a regulation passed in December last, assistant surgeons in the American navy are entitled to mess and have quarters with the wardrobe officers. Why should not equal justice be done to our own naval medical officers, who are equally meritorious, and whose services in time of war are of the utmost importance to the country.

Two children, named Ginniver, twins, aged four years, living at Wassall Grove, Worcestershire, with their parents, were troubled with ringworm; their mother had them treated by Mr. Welch, a Stourbridge druggist, who supplied her with a liquid wash. This preparation skinned her own hand, and salivated the children. Blood and saliva flowed from the mouth—the head and scalp were ulcerated—the cheeks tumefied, ulcered, and gangrened—swallowing became impossible—purging and vomiting ensued—and death terminated the sufferings of the patients. On a *post-mortem* examination, the morbid appearances were such as present themselves in persons who have been poisoned by corrosive sublimate. The druggist has been committed for trial on a charge of manslaughter.—*Gateshead Observer.*

Drs. Scott and Turnbull have been elected Physicians to the Northern Hospital. Dr. Sutherland was an unsuccessful candidate.

Our readers have not failed to notice, that in the details of the late duel at Gosport, the startling announcement is made, that—"Mr. Hills, chemist, of ——— Street, Portsmouth, sat up with Mr. Seton" (the wounded man) "the whole of last night." The surgeons who had charge of the case, will do well to explain to their brethren the cause for so unprofessional a course—a course, which, if a medical attendant was at all necessary, *endangered* the patient's life?

The Manchester Medical Reform Committee held a meeting on the 20th instant, and have carried a resolution to the effect, that the Amended Medical Bill requires modifications. First, in the initiatory Examining Board, in which the proposed New College should be duly represented: and secondly, on the members of the New College being allowed to retain on the proposed register, their present title of Surgeons: and thirdly, in the New College being placed on an equal footing with the other colleges. If this position is not guaranteed to the General Practitioners by their proposed Charter of Incorporation, and by the Bill, the Committee pledges itself to oppose their further progress.

Mock meetings have been got up during the week against the National Association by a person, excluded, with much deserved ignominy, from the Committee of that vast society. One of the British Medical Association numbered—we are told—eight persons, and more than one of these, including Dr. Webster, felt it necessary to withdraw themselves from the proceedings.

The rumours of cholera at Sheffield turn out to be but of trifling importance. One fatal case in a workhouse, followed by a little illness among the women, the consequence of their fears, is all that really occurred.

A SELECT PRACTICAL FORMULARY.

TRANSLATED FROM THE FRENCH OF M. FOY, PRINCIPAL PHARMACIEN OF THE HOSPITAL SAINT LOUIS, AT PARIS.

(Continued from page 132.)

Syrup of Laffecteur: a syrup, the composition of which is scarcely known, but which has considerable analogy with the compound syrup of sarsaparilla of the Codex (syrup of Cuisinier), and which the formulary of Cadet indicates as being prepared with sarsaparilla, china-root, guaiacum, yellow bark, molasses, sassafras, aniseed, and borage flowers. Mode of exhibition: one to three ounces in the day pure, or in a little ptisan, as anti-syphilitic and anti-psoric.

——— of Milk (Robinet): a syrup composed of new milk, skimmed, and concentrated by evaporation, cherry-laurel water, and sugar. Scarcely ever used.

——— of Lettuce: a syrup prepared with one pound of distilled lettuce water, and two pounds of sugar; recommended as a sedative in the dose of from half an ounce to an ounce by Messrs. Martin Solon, and Soubeiran.

——— of Larrey (Formulary of Military Hospitals): thirty two pounds of sarsaparilla, two pounds of borage, two pounds of pale roses, two pounds of senna leaves, two pounds of green aniseed, one pound of elder-rob, sixty-two pounds of sugar, and a sufficient quantity of water, containing in each pound five grains of corrosive sublimate, five grains of sal ammoniac, and five grains of watery extract of opium, to be added at the moment it is used. Mode of exhibition: one ounce daily, in constitutional syphilis occurring in weak and lymphatic subjects.

——— of Lupuline (Magendie): four ounces of simple syrup, one ounce of alcoholic tincture of lupuline, mixed together. Mode of exhibition: half an ounce to an ounce in potions, juleps, or mixtures—used in the same diseases as hops.

——— Gummy Mercurial (Lagneau): twenty four grains of mercury, one ounce of powdered gum-arabic, one ounce of compound syrup of rhubarb, rubbed together in a glass mortar until the mercury is quite killed, then three ounces of syrup of marsh-mallow added. Mode of exhibition: half an ounce to an ounce in the treatment of venereal diseases in adults; a coffee spoonful daily for very young children.

——— of Mulberries: a slight stimulant, prepared with sixteen parts of the juice of mulberries, and thirty parts of white sugar. It is used in the dose of from one to two ounces, in gargles, in cases of mucous angina.

——— of Opium (Codex): simple syrup, containing one grain of the extract of opium in the ounce.

——— of Opium, succinated, see syrup of Karabe.

——— of Orgeat, see syrup of almonds. Syrup of orgeat and milk is the common syrup of almonds, with the exception that the water is replaced by new skimmed milk, and it contains cherry-laurel water.

——— of White Poppies, see syrup of Diacodium.

———, Pectoral Demulcent (Selle): one ounce of liquorice juice, dissolved in eight ounces of camomile water, to which is added two pounds of syrup of marsh mallow. Mode of exhibition: by teaspoonsful several times in the day, to assist expectoration in catarrh and pulmonary phthisis.

——— of Asparagus Tops: two parts or two pounds of white sugar dissolved in a water-bath, in one part or pound of the depurated and filtered juice of asparagus, and strained through a piece of cloth. Mode of exhibition: one to three ounces daily, in a little water, as a sedative on the circulation, in cases of palpitation, affections of the heart, ascites, influenza, &c. Its utility has been exaggerated, and we may say the same of the extracts prepared from the roots and tops of asparagus.

——— of Polygala (Pharmacopœia of Louvain): one ounce of Virginian polygala, digested during twenty four hours in nine ounces of water, then filtered, and eighteen ounces of sugar dissolved in it. Mode of exhibition: by teaspoonsful in chronic affections of the chest. It may be given pure or in a little water.

——— of Bark in Wine (Codex): seven drachms of the soft extract of bark, one pint of Lunel wine, one pound and a half of sugar, made into a syrup by means of a water bath. *** A febrifuge containing twelve grains of the extract of bark in the ounce.

——— of Ergot of Rye: one ounce and a half of powdered ergot of rye, macerated for seven or eight days in eleven ounces of white wine, filtered, and a pound of sugar dissolved in it by means of a water-bath. Mode of exhibition: half an ounce every ten minutes in protracted labours.

——— of the Subcarbonate of Potash (Puche). one ounce of subcarbonate of potash, four drachms of mint water, one pint of simple syrup, mixed together. Mode of exhibition: two ounces to the quart of mucilaginous ptisan. Used in the commencement of blenorhagia, in cases of catarrh of the bladder, gravel, &c.

———, Compound Sudorific: see syrup of Cuisinier, or the compound syrup of sarsaparilla.

———, Simple Sudorific: twelve ounces of sarsaparilla, twelve ounces of guaiacum, six pounds of sugar, eight pounds of common water, made into a syrup, secundum artem. Mode of exhibition: two to three ounces to sweeten a quart of anti-syphilitic ptisan.

——— of the Sulphate of Morphia (Magendie). simple syrup containing one grain of the salt of morphia in four ounces. Mode of exhibition: half an ounce to an ounce as a sedative, in potions, juleps, or mixtures.

——— of the Sulphate of Quinine (Magendie): simple syrup containing two grains of the salt of quinine in each ounce, with the addition of a few drops of sulphuric acid (diluted?) Mode of exhibition: half an ounce to an ounce every two hours in intermittent fevers, and as a tonic.

THE MEDICAL TIMES

No. 298 SUMMARY. June 7

COURSE OF LECTURES ON THE THEORY AND PRACTICE OF MEDICINE.

Delivered by C. J. B. WILLIAMS, M.D., F.R.S., Professor of the Practice of Medicine, and of Clinical Medicine at University College.

The symptoms more distinctly called hysterical, are shown by the affection constituting the more regular form of hysteria, independently of other diseases; sudden changes from laughing to crying, and various convulsive actions; sobbing, with choking, as if there were a lump like a ball in the throat, constituting *globus hystericus*; spasms connected with a quantity of wind; there is a great noise of wind inside, so loud as to be indelicate; palpitation very commonly occurs, and various other feelings of disordered sympathies; together with this, the mind is disordered, and there is dyspepsia, a tendency to exaggerate sufferings, something like hypochondriasis. All these things may be wound up to the highest degree, so as to constitute a fit; rolling of the eyes, and spasms of a tetanic character, rigidity, &c. It is remarkable, with regard to these affections, that persons do not lose their consciousness entirely, generally speaking. Sometimes, instead of the convulsive affections, there is stupor, and sometimes delirium, the sensorial function being more affected, and sometimes there is apparent syncope, and yet, at the same time, the heart is beating violently. This is one of the instances of fits producing loss of consciousness by an irregular distribution of the blood; not at all an uncommon form of hysterical fit. When the patient comes to herself, she sighs, and sobs, and there is a copious flow of limpid urine, as in other cases of nervous irritation and nervous diseases, accompanied by an increased action of the heart. I believe the increased flow of urine is owing to the increased rapidity of the circulation especially affecting the kidneys; the urine is increased in the watery contents, but not in the urinous principles. More permanent affections are left after these fits, such as partial paralysis, affecting the side, one arm, or one leg. There is not complete paralysis. Sometimes, too, various nervous affections remain permanently, such as palpitation, irregular action of the heart, asthma, and a flatulent disposition of the abdomen. Besides these peculiar hysterical conditions, there are various functional disorders of sensation, and the sensorial faculties; spasm of the glottis, affections of the respiratory apparatus, and the urine is altered; sometimes there is loss of the power of articulation; pains of the chest, and various characters of dyspnœa, violent coughs of different descriptions, spasm of the diaphragm affecting the breath, and causing a violent catching; affections of the intestinal and alimentary canal, dysphagia, retching and vomiting, pain in the abdomen, particularly in the left hypochondria, more rarely the right hypochondria, or sometimes in the iliac region; constipation, sometimes very obstinate, sometimes only arising from retention of feculent matters; disordered secretions of the alimentary canal are commonly found in connection with hyteria; affections, too, of the urinary organs, *dysuria*, are very common, the lithic acid being in great quantity, and sometimes the opposite condition, a deposition of the phosphates. There are left after the fits, besides these peculiar symptoms, trismus, tetanic spasm of the jaw, continued action of the heart, and neuralgic pains on the surface. Spinal irritation is a variety of hysterical affection; the knee is particularly irritable or sensitive, this is called hysterical affection of the knee-joint.

I think you will now see by this very summary view of the symptoms of hysteria, that there is always, more or less, some anomalous condition of some of the functions of the nervous system, and probably through these, other functions are disordered; the function of the circulation of the blood, for example, and the secretions and excretions, and various other functions.

Well, now let us advert, shortly, to the predisposing causes of hysteria. I have already mentioned, that females are generally predisposed to hysteria at the menstrual period; though this is not essentially so, but where other circumstances favour the development of the nervous properties; and they may occur in the male sex, and independently of the menstrual period in the female sex. A nervous temperament is a predisposing cause; a sanguine temperament may be considered to predispose to hysteria, because it is more excitable. Subjects who are called delicate, whose functions are easily disordered under circumstances of an extreme nature, are liable to become hysterical, because there is an undue development of the nervous system, while other parts are reduced in strength. Effeminate, or childish habits, lead to the hysterical diathesis; and so do confinement and sedentary habits, particularly where these are combined with animal excitement. The various pursuits females especially devote themselves to, novel reading, frequenting theatres, and exhibitions, by which their feelings are strongly wrought upon,—these are circumstances that act as predisposing and exciting causes of hysteria; so, likewise, late hours, and warm clothing, and excessive heat. The education of females, as it is usually conducted, must be considered as one of the most powerful predisposing causes of hysteria that can be conceived. If you conceive the manner in which the properties of the nervous system are exaggerated, and are cultivated, as it were, at the expense of the bodily strength, the manner in which the whole of a female's attention and anxiety are engrossed by occupations, the object of which is to excite admiration, you can readily understand why females are predisposed to hysteria. Just consider what boarding school education is! It is an employment, the chief desire of which, is to please, to produce effect, to gratify vanity, much more than to answer any truly beneficial purpose in life; and so when the best part of a child's years is devoted only to these pursuits, and when the mind, and all the faculties, moral and intellectual, are, as it were, devoted to this, it is no wonder that the nervous system and its various functions, should have the preponderance over bodily strength, which is often quite neglected. The vanity has been cultivated in the highest degree by the acquisition of expensive accomplishments, as they are called. This vanity is destined either to be gratified or to be mortified, and under these circumstances comes the great struggle of the mind and the moral feelings, in which the nervous system becomes unduly excited; and when they are called upon to suffer disappointment, then it is that this undue development of the nervous system proves a predisposing cause, upon which we find hysteria mainly to depend. The relation of the uterus to hysteria is very important. Important as this function is in the female, no great change can take place without the uterus being affected; and where the function is affected, so as to be interrupted or disturbed in any way, it is no wonder that this re-acts as a cause of still further disorder, and hence there is no wonder that the aggravations of hysteria should cease when the disorder of the uterus is diminished or relieved; and in advanced life, when the uterine period ceases to be active, and likewise in some cases of pregnancy; it is from these circumstances that the common form of hysteria arises. The best remedy for hysteria, is for females to marry and bear children. This is explicable in a very obvious way; the mind as well as the body becomes occupied by proper objects; the common purposes of life are not those, generally speaking, that draw out to a high degree or unduly develop the nervous system; other matters are to be attended to, which prove a healthy stimulus to the mind and body, which are both actively employed; the body is physically engaged in the function of parturition, and so forth. In many cases, however, a fruitful marriage is not a cure for hysteria, particularly where it has been exhibited most decidedly in connection with a nervous temperament. I have known women who have remained hysterical even after a fruitful marriage. There is another proof that the uterus is not essentially the cause of hysteria: we find uterine disease of every description, both functional and organic, without hysteria. It is very common in *amenorrhœa* accompanied by *anæmia*. It is extremely rare to find hysteria developed much in connection with organic disease of the kidneys, or of the ovaries, or even inflammation of those organs. Uterine disorder obviously, sometimes, causes hysteria in an indirect way, not by mere sympathy, by supposing that it is the sole origin of the hysterical symptoms. For instance, suppression of the catamenia is apt to be followed by hysteria, but that is by producing a plethoric state of the system. It has been followed by coma, or paralysis in other instances. Menorrhagia or amenorrhœa has been sometimes followed by nervous symptoms, nearly in the same way as other great disturbances, by exhausting the body. Hysteria is sometimes present without any sign whatever of diseased uterus, either functional or structural, whereas other functions are disordered; as for instance, the alvine function, the stomach and the intestinal canal, which is frequently the source of disorder of the uterine function; and it occurs in connection with constipation of the bowels. There are symptoms called hysterical, often conjoined with disordered circulation; partial congestions of the different organs occurring in a nervous temperament, produce what are called hysterical affections. The same thing occurs with regard to structural disease, particularly of the heart and lungs. Persons who are not nervous men, have a great

amount of structural disease of the heart without presenting any symptoms of hysteria. The exciting causes of the symptoms of hysteria, are sometimes the predisposing causes I have mentioned, and there are others that operate as exciting causes of the convulsive form, particularly imitation, and this has been observed to prevail in schools. Hysteria appears to be essentially a disorder of some function of the nervous system, either congenital or as the result of disease, or circumstances unduly exciting the nervous system; outward circumstances affecting the health, or inward circumstances affecting the mind and the moral feelings, even when there is no serious disease in the nervous system itself. But this excitability of the nervous system sometimes produces symptoms, more or less marked, of serious disease. There is a changeability or mutability in persons who have exhibited always, more or less, of these nervous properties, and they go on week after week, month after month, year after year, without leading to any serious results, which would occur were the disease what it appears to be. I have adverted to the fact, that not only the bodily functions, but the mental also may be seriously involved in these morbid affections of the nervous system, and there can be no doubt that there are some kinds of mental derangement of an imperfect and irregular kind which solely arise from this. Hysterical delirium, for instance, is a very common symptom in hysterical subjects. There is a remarkable development of different feelings connected with sympathy: persons are exceedingly anxious to attract notice to excite sympathy, and to feign diseases, in which they exhibit an astonishing degree of ingenuity; they have been found to blister parts in a secret way, to run needles into their limbs in order to deceive others; this is something bordering on monomania.

The diagnosis of hysteria is very difficult. Attention to the previous history, of there having been exhibited some proofs previously of nervousness, observing whether the nervous symptoms predominate, and comparing the nervous symptoms with other derangements in the body; the mutability and the varying character of the nervous affections, are the means of arriving at a diagnosis, or whether it is of a fixed kind, such as hysterical affection in the knee joints, or hysterical pain in the side. In cases of convulsive hysteria constituting fits, it is distinguished from epilepsy by the attack coming on less suddenly, being preceded by nervous symptoms, such as *globus hystericus*, by there not being the scream, which often occurs in epilepsy, by there being some remains of consciousness during the paroxysms, and also by the care which the patient takes of herself, never biting her tongue nor falling down in an uncomfortable or indelicate position. Again, the pupils may be observed to be more sensible to light, and not contracted nor dilated; no foaming at the mouth; the convulsions are more of the upper extremities than of the lower—throwing about the arms and the hands, and rolling the head, more than tetanic and violent convulsions. There is, too, a disposition, on recovery from the fit, to laugh and cry, with hysterical sobs; there is also a remarkable excitement of the mind, which is absent in epilepsy. But it must be remembered that hysteria may pass into epilepsy, and in some cases into apoplexy, but this is extremely rare. The diagnosis of the local affections of hysteria which simulate the other diseases I have alluded to, is to be distinguished chiefly by the absence of much heat and the predominance of nervous symptoms, and excessive sensibility, causing the patient to cry out before being touched, and extreme sensibility when attention is directed to the part. In sleep the part may be touched with considerable force without waking the patient, which can never be done in cases of real inflammatory pain. The symptoms that are present are altogether too intense for the other signs of the disease.

The prognosis of hysteria is extremely variable, but generally speaking, the symptoms are in undue proportion to the real disease, and therefore the prognosis is favourable as to its fatal termination; although there is scarcely any risk of their terminating fatally, it is exceedingly difficult to get rid of these hysterical affections, which are extremely tedious.

The treatment varies according to the causes, and the constitutional states in which the disease occurs, and according to the different forms that are presented. The general treatment should be applied more or less, in every case; that is, the exalted or nervous properties are to be treated, to deaden the sensibility, and quiet the excito-motor function, and to strengthen the tone of the whole system, so far as it can be done. The indications are often opposing ones; it is often indicated to restore the strength, and to diminish the excitability of the nervous system, at the same time that the functions of digestion and deglutition are so weak, that we have not the means of accomplishing the end; hence it is, that frequently the treatment of hysteria becomes exceedingly tiresome and distressing. In convulsive hysteria, where the fits come on in a more regular form, cold affusion on the whole body will often stop them, it being both a physical and a moral agent. Cold affusion on the head and face will suffice, and this acts partly as a physical agent, by diminishing the determination of blood to the head and neck. Anything producing any very strong impression will do; a smelling bottle, a pinch of snuff, and ammonia will restore a sensitive girl to consciousness. The same thing may be said with regard to valerian, assafœtida, or fœtid spirits of ammonia. In case of trismus, turpentine injections have been found to be useful, and it is a very good remedy particularly in tetanic hysteria; where there is any plethora, and the fit seems to be connected with fulness of the whole habit, it may be necessary to draw blood. To prevent the recurrence of the paroxysms, anything to draw off the attention of the patient will frequently succeed. Excessive pain should be treated according to the state of the circulation, and in females in relation to the uterine function. The uterine function has a very important relation to the whole frame of the female. If the menstrual discharge be defective, the treatment will vary, according to whether the body is plethoric, and if not, tonics should be given with mild purgatives and derivants, to cause some determination of blood to the neighbourhood, and promote the return of the discharge. Iron and aloes are useful in some cases; in many cases iron is not good, and in these, iodide of potassium in combination with decoction of aloes is very useful. Sometimes together with the absence of the catamenial discharge, there occurs congestion, and a tendency to hæmorrhage, and under these circumstances sulphuric acid, and saline aperients, together with bitters, are to be employed. In cases where the catamenial discharge is absent, and there appears to be weakness, connected with a congested state of the uterus, local depletion is very useful. A generous diet, and regular exercise, as much as the patient can bear, particularly on horseback, are highly beneficial when the function of the uterus is defective. In some cases I have found hysterical symptoms occur in connexion with a too frequent or too copious menstruation, sometimes connected with weakness, produced in other cases apparently by uterine irritation. The patients in such cases should confine themselves to the horizontal posture, using saline and alkaline purgatives. In cases of dyspepsia connected with hysteria, it may be treated according to its kind. If it is of an inflammatory nature, blue pill, hydrocyanic acid, and carbonate of soda, with local depletion are useful remedies; and very soon for these may be substituted remedies of the tonic kind. In cases of hysterical spasm of the glottis, or hysterical asthma, the various anti-spasmodics are to be used, belladonna, stramonium, oxide and sulphate of zinc, and in anemic cases, preparations of iron. Hysterical headache is generally of the congestive kind, accompanied by imperfect circulation, and this is relieved by stimulant remedies, cold to the head, and warmth to the feet. Pain at the left side is often very troublesome, and may require the application of a blister; it is not desirable to draw blood, in most cases. In connexion with feverishness, blistering the part may be necessary, and in many such cases, where there are local pains, local blood letting may be applied to that part of the spinal column, where the pain is. Retention of urine may be remedied by turpentine injections and tincture of cantharides. Palpitation may be removed by hydrocyanic acid and other anti-nervous remedies. Hysterical affections of the joints may be relieved by counter-irritants, such as the camphor liniment, with tincture of opium. No treatment is so effectual with regard to the hysterical diathesis as that which tends to reduce the nervous sensibility, by relaxing habits, early hours, not sleeping too much, open air exercise, and cold bathing.

COURSE OF LECTURES ON SKIN DISEASES,

By D. J. Corrigan, M.D., Physician to the Whitworth, Hardwick and Richmond Hospital, Lecturer in the Dublin School of Medicine, &c.

Gentlemen,—The next disease which I shall take up will be impetigo, though in doing so I deviate from the arrangement which I have marked out for myself, according to which porrigo should come first; however, for reasons which I shall hereafter explain, porrigo will be left to the conclusion of pustular diseases. I have already made you acquainted with the characters of the pustules which appear in impetigo; these are of the kind called psydracious. I shall not on the present occasion plague you by going over them again, but shall merely remind you of a fact which I have endeavoured to impress upon you before, that in no other disease but impetigo, do you ever meet with the psydracious pustules. This disease is very frequently met with in Lying-in-hospitals and children's dispensaries; it attacks persons of all ages, and every part of the body; children are those in whom it principally appears, and the face and scalp the quarters it usually selects. In these plates you have it as it appears on the latter situations, constituting the crusta lactea of Bateman. In these plates of Alibert's you may perceive the peculiar appearance of the pustules of impetigo, before the scabs have been removed by any application; they are of a greenish yellow colour, softish, and slightly elevated above the skin by a deposition of successive layers of scabs formed by purulent matter secreted from the cutis vera. In this drawing, taken from a child labouring under the disease, you have an opportunity of seeing the appearance presented when the scabs have been removed. You can almost see every pore of the raw and reddened surface which has been exposed, pouring forth the peculiar viscid and honey-like secretion which is thrown out to form the scabs in this disease. Looking at these children, this one in particular (holding up Alibert's plate), you would at once say that it could not escape without very great deformity. But this does not occur; no matter what length of time the the disease may exist, whether for one month or for four (and do your best, and try what you can with it, it sometimes takes the latter period of time to remove it), or no matter how thickly the face may be covered with it, still it never leaves the least deformity or mark behind it. The reason is obvious, when we know that it is the cutis vera which continues to secrete the pus during the progress of the disease. The inflammation does not travel beyond this, consequently no cicatrices are formed to mark the child. It is easy to understand, that owing to neglect on the part of mother or nurse, a child affected with impetigo may, by scratching, produce ulceration of the cutis vera and parts beneath, thus giving rise to cicatrices: but this is not the effect of the disease. This disease is said in books not to be contagious; now, I assert the very reverse, and say that it is, as I have seen it spread from one member of a family to another; even these drawings prove to you its contagiousness. We perceive pustules produced on the cheeks by the dropping upon them of the matter secreted on the forehead, and we find the neck becoming encircled with a pustular belt by the dropping of the purulent secretion from the chin on the latter part, and in many instances, we find it conveyed by the child's fingers from one part of the body to another.

This disease is peculiarly liable to appear in spring, when, unless guarded against by rigid cleanliness, it will attack all who may come in contact with it; by its occurrence in spring it would seem in some measure to support the popular belief, that this season predisposes us to eruptive diseases, and, indeed, more or less to diseases of every sort. How to account for this fact I am at a perfect loss, but am well satisfied of its accuracy. I know a young patient, in whom the disease appears as regularly as the spring comes round; a few pustules appear on the face, which would very soon spread further, were they not removed by appropriate treatment. I also know another, who, in spite of all I could do for her, remained affected with it for five years, until beyond the reach of every source of irritation from teething; her first dentition was not complete until she had acquired the above age.

According to systematic writers there are a great many varieties of impetigo, but by bearing in mind the grand criterion of the disease, you can never mistake any of its forms.

There is a form of it, or rather, a connecting link between it and eczema, named eczema impetigenodes, where we find the skin rising off in scales, while a scattered pustule here and there over the part, exhibits its analogy to impetigo. This form generally attacks the extremities, as you see in this drawing, taken from a case in the Whitworth Hospital, to which I have already called your attention. Impetigo may assume any irregularity of shape on the body; and again we often find it assuming forms as tortuous as the patches of psoriasis gyrata.

When called in to treat this disease at its first appearance, you will in general find it yield to the employment of mild alteratives. The medicine which I am in the habit of ordering on those occasions, is one composed of two grains of hydrargyrum cum creta, with four or five grains of bicarbonate of soda. This is to be persevered in every night regularly for some time after the disease has disappeared. Along with this you will derive a very great advantage from the use of an ointment of carbonate of lead, employed as long as any irritation exists. I have heard a great deal of the danger of using preparations of lead over such an extent of surface as is exposed in this disease, but I must say, that I have never seen any such, and until I am convinced from experience that such does ensue, I shall continue to employ them, and I advise you to do the same, as you would derive more benefit from their use, than from any other application which you can prescribe. When the existing irritation has been removed by the remedies just now recommended, you may, with advantage, add to this ointment some slight stimulant, and the one which I find answer best, is carbonate of soda, in no greater proportion than five grains to an ounce of cerussa ointment; along with these means of subduing the disease, you will derive very great advantage from the use of a bran bath; this is made by throwing a few handsful of bran into some boiling water, straining it frequently, and, after some time, adding it to the water of the bath, to which it imparts a slight glutinosity; this acts as a mild sedative to the exposed portions of true skin; but there are cases where, as I have remarked already, this plan of treatment will fail, and when, notwithstanding all you may do, the disease will continue for a length of time. Here you must have recourse to an alterative of higher power than the one before recommended. In this state of things, I know of none better than hydrargyri bichloridum given in very small doses, and continued for a length of time. For a child of two years old, the dose should not exceed 1-36th of a grain three times a day. Recollect that you do not want to induce salivation, you only require a medicine capable of completely altering the child's constitution, and this you possess in corrosive sublimate given as I have directed. It is unnecessary for me to mention that the strictest cleanliness must be enjoined, and that the members of the family who may have caught the contagion should be carefully kept apart from the rest. In any case of severity or long standing, you should, if possible, have the child sent into the country.

The last disease, gentlemen, of the class pustule is porrigo; this I have kept for the last, for reasons which I shall presently mention. In none of the books on medicine which I have read, or am acquainted with, have I ever met with a genuine and true description of porrigo, this disease either having been mistaken altogether, or confounded with others with which it has not the slightest affinity, and from which it should be kept widely separate. Porrigo is stated by writers on skin diseases to be contagious, while impetigo is said not to be so; but this I deny, and maintain the converse, that impetigo is contagious, while porrigo is not at all so. It is to expose, as I trust satisfactorily to you, the errors which have crept into systematic works on this subject, that I have deviated from the arrangement which I proposed to myself at the commencement of these lectures, errors which have led persons to claim credit for remedies of various kinds as possessing the power of curing genuine scald head, a power which has been erroneously ascribed to them, and which they do not possess; it is to correct these errors, and to prevent you from attaching any credit to such statements, that I proceed to address you upon the subject of porrigo; and the remarks which I shall offer are the result of observations of this disease, carefully made, and drawn from a practical acquaintance with it, as extensive perhaps as that of most medical men.

All the writers on skin diseases, from Willan to Bateman, and from Bateman to Biett, have erred in their description of porrigo; in fact, they seem to know nothing whatever about it, for under the head of porrigo, they have described various diseases, differing from it in every particular. Under the name of porrigo they have described various forms of impetigo, as it attacks the scalp and other parts of the body, while they have not given a history of porrigo as it really presents itself. Though the above-named writers have made the matter bad enough, still they fall far short of that confusion into which Mr. Wilson has thrown this subject, whose work on Skin Diseases I believe is the latest extant. This gentleman has invested the matter with such an air of learned obscurity, that the man who could recognise genuine porrigo from his description, should indeed possess extreme clearness of comprehension. You will read in it that this disease is one of very great frequency; now, if such be the case, it is wonderful how any one could err in describing it; we shall, however, by and by see, that so far is this from being the case, that on the contrary it is singularly infrequent above all other skin diseases, and almost equally singular in its difficulty (I should rather have said impracticability) of cure. Bateman, in his clever work on Skin Diseases, has made no less than five varieties of porrigo, namely, P. Larvalis, P. Favosa, P. Scutulata, P. Decalvans, and P. Lupinosa. Let us examine each of these varieties, and in so doing test the Doctor's accuracy of description in this disease. Let us take his own description of each of the first three varieties, and we shall find them to be neither more nor less than so many varieties of impetigo, differing in its characters according to the parts of the body on which it may appear, or according to the shape it may assume. The P. Larvalis of Bateman (his own crusta lactea) is nothing more than impetigo affecting the scalp, and has no relation whatever with porrigo. The next, P. Favosa, has just as much claim to rank with porrigo as the first, being in fact, nothing but impetigo attacking the scalp, and presenting the characteristic soft, greenish yellow scab of the latter disease. The next, P. Scutulata, has been most absurdly named from the shape which the clusters of pustules may assume when they scab over; this, too, possesses all the essentials of impetigo, and not one of the marks of genuine porrigo. It would be just as proper for a writer to make varieties of pneumonia from the number of lobules of lung affected, whether these might be one, two, or three; or to invent a thousand new and previously-unheard of divisions of small pox, based on the number of pustules which might be grouped together, as these might chance to be in threes, or fours, in twenties, or thirties.

These varieties may be blotted out of the list altogether. The next variety, P. Decalvans, is merely atrophy or wasting of the bulbs of the hair, when the hair falls out, and the person becomes bald. This disease to which the name of porrigo has been most absurdly given, is all through its progress completely free from the slightest trace of pustulation. It is really too bad to find authors, writing ostensibly for the instruction of others, committing blunders, which the merest tyro in the study of diseases could not possibly be guilty of; you take up one of these works on skin diseases, you open it at the heading of pustules, you find certain rules laid down there by which you are to recognize this class of diseases whenever you meet them, yet in another part of the same work, you find the author describing as a pustular disease, one which by his own description, confessedly does not possess a single character to entitle it to rank with the above class of diseases. No wonder, that the student on perceiving such inconsistencies, should become altogether disgusted with the subject, and throw up its study in despair. Into an error such as I have mentioned, Bateman has fallen. The fifth variety, P. Lupinosa is really porrigo, but in his description of it, Bateman has committed inaccuracies. Here I must put you on your guard, and inform you that this P. Lupinosa of the English is the P. Favosa of the French writers. It would seem as if the sole object of every writer on skin diseases were to try which of them could puzzle us most by inventing the greatest number of new names for new varieties. Just do as follows: recollect that there is such a disease as porrigo. Make yourselves masters of the means of distinguishing it when you meet it (and which, let me tell you, will not be very often,)—just do this, and never mind the varieties.

Were I inclined to make any alteration in the existing arrangement of skin diseases, it would be that of removing porrigo altogether from the list of pustular diseases, and forming it into a class by itself. This, the very peculiar character which it possesses, would fully entitle it to. Porrigo is an affection, which having once seen, you cannot by any means forget. Its whole appearance is so characteristic, and so completely different from that of any other disease, as to stamp it with an impression which you cannot ascribe to any other malady. It is liable to attack all and every part of the body, and to assume every fantastic variety of form which marks the patches of lepra or psoriasis.

In fact, as I have just said, it may appear in any variety of shape. Do not be led from this to make new varieties of it. Recollect that no matter where it may appear, or what forms it may assume, it is still porrigo. Here you may perceive the disease in a chronic state, (holding up a drawing) where from the accumulation of scab upon the scalp above the hair, the head presents a white powdery mealy appearance, or this appearance may, with more propriety, but less elegance be likened to that presented to you, were a piece of mortar stuck on the head and allowed to dry there. On friction, part of it would be reduced to fine white powder, and would present the appearance which I have endeavoured to convey to you, and which this drawing so admirably represents. This is the P. Lupinosa of Bateman. Some years ago, (and I do not know, but the custom still exists) it was usual for paupers to go round the country with their heads shaved, and exhibiting these masses of porrigo, for the purpose of exciting compassion. I fancy that at present they would gain but little by such a system of exhibition.

I shall now proceed to tell you, how porrigo appears in all its stages. When by poultice or any other means you remove this coat of scab, you find the skin beneath red and seemingly healthy; this drawing shows it very well (handing it round); this series of drawings was taken in the Whitworth Hospital from a young man affected with porrigo, (Peter Conran ætat 17.) This state of the parts may continue for a fortnight, or perhaps longer, and you may suppose the person well: but if you now examine the skin of the affected part, you will perceive a number of minute yellow pustules rising all over it, these pustules generally presenting in the centre of each, the root of a single hair; this latter is of no consequence. The mat-

ter which is thrown out in these pustules (but they can scarcely be called pustules) becomes solid after it has been effused for some short time, often as soon as twelve hours, and again, not for a lapse of two days. You never by any chance find in or beneath the incrustations of porrigo, the smallest quantity of fluid matter. This is the grand criterion of the disease above all other cutaneous maladies, with which it might be confounded. You examine the scalp, and you find these appearing; they in general are but little elevated above the skin, sometimes on a level with it, and occasionally they are depressed below it, or, to speak more correctly, the centre of each pustule is depressed, while its edges are elevated to a level with the skin. This gives the pustules a cuplike appearance. When these appear in a circular form, they encroach upon one another, and in so doing, obey a law which all circular bodies do when they impinge upon each other; that is, the form of the circle is changed to that of a hexagon, so that the surface on which the eruption may appear, presents a similar appearance to that of a honeycomb viewed laterally, Let us pause here to examine the diseases with which it may be confounded. Systematic writers, as we have already seen, describe impetigo for it, and it may be mistaken at this stage for eczema of the scalp, or for sycosis attacking the same place. Just keep the characters of each in mind. If you are in doubt as to the nature of the straw-coloured softish scab of impetigo, remove it with a poultice, when you will find the skin beneath pouring out the honey-like fluid, which when dry, constitutes the scab. Now take off the white powdery scab of porrigo, and you have the red skin not secreting matter, but which, in ten or twelve days, will be again covered with pustules as before, and the solid nature of their contents will place the question beyond all doubt. Eczema also presents a moist surface, and sycosis of the scalp will be easily recognised by the phlyzacious character of the pustules. When this stage has continued for a few days, the scabs gradually acquire additional thickness from layer after layer of the solid matter being secreted underneath. Observe what a difference in the appearance of these two drawings (one of crusta lactea, the other of porrigo of the face) no one could possibly mistake them for one another. This disease, porrigo, differs not only from all others in the character of the pustule which is solid, but also in the chemical nature of the matter secreted. This consists of a mixture of coagulated albumen, carbonate, and phosphate of lime. In this drawing, admirable even as a work of art, you have a capital delineation of the disease as it appears on the trunk. Not only has the artist succeeded in representing the disease faithfully true to nature; but, more difficult still, he has succeeded in hitting off admirably the peculiar expression of countenance presented by those labouring under the disease. You cannot but observe in all this series of drawings an expression of countenance betokening, if not fatuity, at least a very great want of intellectual power; they are all persons of a heavy stupid look.

Once for all bear in mind, that the characters of porrigo, are, an eruption of minute pustules, the matter in which after a day or so becomes solid, this collection of matter becoming larger and larger every day from new secretions, until at length the whole mass, if the scalp be affected, rises above the hair, presenting a white powdery surface. Remove this incrustation, which you can easily do with a poultice, and, in a few days more, you will find a fresh crop of pustules springing up to run through the same course as the previous ones. This disease is said to be contagious. I deny this, for were it so, it would be a disease of much more frequent occurrence than it really is. Nothing can exceed the facility which the customs of persons in the lower ranks of life afford to the transmission of the disease, were it contagious. If it were so, it would appear very frequently in them from the habit they have of wearing their hats, caps, &c. in common, as well as the other articles of dress, which are used indiscriminately among them. Whenever impetigo appears in a family, it is sure to run through the whole of them. If one child only use the brush, comb, or towel, which had been previously used by the affected child, he is sure to have it. It is even propagated by contact with the child's hands, in consequence of their being imbued with the matter of the pustules. Even the nurse or mother will be sure to suffer from this cause, if very great care be not taken. I can confidently state that I have never seen porrigo attack two persons in the same family. My experience of it has not been very extensive; but meagre though it be, I reckon it equal, if not superior, to that of any other medical man in the city in the same disease. For many years I enjoyed opportunities particularly favourable to the study of skin diseases of every sort; and though possessing such advantages, I can confidently assert that, in all that time, I have not seen more than a dozen cases of it; and were I to limit myself to half the number, I think I should be nearer the truth.

We shall resume this subject on another evening.

SYPHILIS IN INFANTS.—Dr. King, of Eltham, Kent, has sent us the details of the following cases, as illustrating the paper by Mr. Acton, read at a late meeting of the Royal Medical and Chirurgical Society. The cases were alluded to by Dr. King at that meeting. Mrs. P——, the mother of several healthy children, about the latter part of the year 1842, was delivered of a child, which was covered with extensive syphilitic blotches, with the cartilages of the nose thickened, and a difficulty of breathing from this cause, to such an extent, as nearly to prevent its taking the breast; it died about the tenth week from its birth, not having been cured of the eruption. The father of this child, unknown to the mother, had about twelve months before been labouring under secondary syphilis, and had not undergone a course of medicine sufficient for his safety, being satisfied with the cessation of the pains in his bones, and the disappearance of the eruption on the surface. About a day or two after the death of this child, a lady, Mrs. I——, living in the neighbourhood, and who had twins, very healthy female children, six months old, whom she was suckling, finding that she was scarcely strong enough to continue this with the two, applied to the mother, Mrs. P——, to suckle one of the twins; thus things went on very well for about a month, when the nurse child became covered with syphilitic blotches, which in the course of six weeks were completely removed by the child's taking eight grains of Plummer's powder in the twenty-four hours, and as much of the fluid extract of sarsaparilla as could be got down, its mother, Mrs. I——, having during this time taken it again, and suckled it along with its twin sister for three months longer. This child has been in good health ever since, and at no time had any soreness of the mouth, nor its mother any sores or excoriation about the nipples. Moreover, the mother of the child that died, says she never had sores about the nipples, but weakness from want of sufficient nourishment, her husband being often out of work, and she was also perfectly unconscious of the nature of her child's malady till a few days ago, when in the presence of her husband's mother, Dr. King informed her of all the circumstances, and that he wished her not to vaccinate her present baby, five months old, as there were some spots about its neck, mouth, and arms, which would require some previous treatment. These copper-coloured blotches, she says, have only made their appearance within the last month, and the child otherwise is plump, healthy, and cheerful, and is suckled by her. This is her second child since the death of the one above alluded to, at ten weeks, and the child next after it died at twelve months from mesenteric disease, she being very unequal from debility to give it sufficient nourishment; it had no blotches on its surface, but had however very dark coloured and inveterate red gum. She and her husband are now in good health, and have nothing to complain of, and the question may with some propriety be asked, is Mrs. P.'s child now labouring under secondary syphilis from the father or the mother. The opinion Dr. King formed in 1843, when she communicated the syphilitic disease to Mr. I.'s twin child, was that the milk was the only medium, as there was no proof that it was otherwise. The "experimentum crucis" would most certainly be to have a healthy child now suckled by Mrs. P——, but this Dr. King is not prepared to try. If it is reasonable to suppose that diseases can be communicated by morbific matters conveyed by the lungs or the surface to the circulating medium, how much more so then must the fœtal circulation render the mother obnoxious to any diseased state of the fluids of the child she is pregnant with, and it is probable also the mother's health may be much influenced through the fœtal circulation, according as the father is a person in sound or in delicate health, thereby rendering the fœtus in utero more or less robust.

REPORTS ON DISEASES OF FEMALES

By EDWARD RIGBY, M.D.

Fellow of the Royal College of Physicians, Senior Physician to the General Lying-in Hospital, Lecturer on Midwifery at St. Bartholomew's Hospital, Examiner on Midwifery to the University of London, &c.

Inflammation of the Cervix Uteri.

Mrs. R. B., æt. 32, mother of two children, but still born.

June 13th, 1842.—Stout, and flabby. Abdomen large, from dyspeptic flatulence; much gastric derangement. Tongue patchy, from mucous irritation. Headache; aching limbs; urine turbid; bowels confined; evacuations light coloured; suffers from piles. Has lancinating pains in the pelvis, and through the mammæ; suffers acute pain during sexual intercourse, and during the passage of solid fæces; albuminous leucorrhœa.

In her first confinement, the child was delivered by perforation, owing to the size of the head. The second was born by the natural powers, after a severe struggle, but died immediately after its birth. She thinks she had an abortion seven weeks ago, and has missed one menstrual period since; but (query) is not this attributable to her anœmic weakly condition.

Examinatio per vaginam.—Os uteri high up and backwards, hard, and intensely painful.

Hirudines viij. ori uteri.

℞. Extracti sarzæ comp. fluid. cochl. med. i., ex lactis et liquoris calcis partibus æqualibus.

℞. Sulphuris precipitati et magnesiæ carb, aa cochl. min. j.; om. mane ex aquâ.

June 20.—Lancinating pains in the pelvis quite relieved, but are still felt occasionally through the breasts; complains of vertex headache: bowels gently acted on by the sulphur and magnesia. As she resides on the sea coast, let her take a short walk every morning before breakfast, and drink a small tumbler of sea water whilst walking.

Contin. sarza c. lacte et liquore calcis.

29th.—Feels better; has continued the medicine regularly, and also her draught of sea water every morning, which has acted gently on the bowels. Has had two warm sea water baths, and has also sponged herself morning and evening with cold water, according to instructions; takes a short walk every morning, and a drive in the afternoon. No leucorrhœal discharge. Occasional darting pain through the breasts; slight pain of stomach, and left hypogast. Urine natural. Tongue much better.

Let her continue the sarsaparilla, and sea water.

℞. Ext. taraxaci cochl. min. ½, o. n. ex lacte.

July 8.—Has menstruated naturally for two days, and feels better. Pergat.

25.—Complains of weakness, want of appetite, &c., which are evidently the result of deranged stomach, from taking too much food. She takes an egg twice a day in milk, besides sarsaparilla three times a day and her ordinary meals, at which her husband continually presses her to take wine and ale, "to keep up her strength," as he supposes; in other respects, she is better.

Omitt. ova cum lacte, et mist sarzæ.

℞. Hydrarg. chloridi gr. iv., extr. hyosc. gr. vj., M ft. Pil. ij., h. s. s.

Seidlitz powder to-morrow morning.

℞. Acid. nitrici dil.: tinct. hyosc. aa. M xv., syrupi aurant ʒj., infus. gentianæ co. ℥iss., M ft. haust. ter die sumendus.

August 1.—Calomel acted only once. Evacuations of a dark green colour. Seems better, but has been suffering under a good deal of mental depression. Repet. hydrarg. chloridum hâc nocte; et cras, horâ somni, sumat ferri sulph. gr. ij.,

extr. lupuli gr. viij., M. ft. Pil. ij. om. nocte sumendæ; as she complains of feeling weak, let her take the morning dose of sea water only when the bowels require it.

16.—Has had a natural return of the catamenia, with, however, a slight degree of pain; evacuations of the same dark greenish colour. Omitt. pil. ferri sulph. Rep. hydrarg. chloridum hâc nocte. Rep. extr. taraxaci h. s. et mist. acidi nitrici dil. ex infuso gentianæ co. ter die.

22.—Calomel produced much nausea, and she vomited a considerable quantity of bile; states that the evacuations are very healthy, but that she still feels a dull pain of the side, which she has not thought worth noticing; let her repeat the calomel pills on the 26th. Rep. mist. acidi nitrici c. gentianâ.

30.—Calomel purged her smartly, but did not make her sick; pain of side has disappeared: is better.

Rep. extract. tarax., et mistura.

Sept. 19.—Her health seems much improved; menstruation has gone on regularly.

This is also a case of inflammation of the cervix uteri, complicated with considerable gastric derangement. Both the habit, as also the habits, of the patient strongly predisposed her to this affection—the stout and flabby appearance, the large and distended abdomen, constipated bowels, and existence of piles, showed an overloaded and sluggish abdominal circulation, and considerable pelvic congestion, as an almost necessary consequence. She was of a peculiarly restless habit, and in spite of frequent requests to the contrary, was frequently upon her feet, even for hours at a time. Moreover, if she was correct as to a very early abortion having taken place, this was, of itself, a strongly predisposing cause of congestion and inflammation of the cervix uteri.

The symptoms of this affection were well marked; the acute pain during sexual intercourse, and the passage of solid fæces, the lancinating pains through the pelvis, sympathetically affecting the breasts; the albuminous leucorrhœa, and the hard and intensely painful state of the os and cervix uteri upon examination, plainly showed the nature of the case.

On a visit previous to the first report, when I had only made out the general facts of considerable gastro-intestinal derangement, I had prescribed her some Pil. Hydr., with a laxative, and some nitro-muriatic acid, to be taken during the day; but it was not until my second visit, at which the report commences, that I was able to elicit from her the uterine symptoms, which, from a false feeling of delicacy, she had previously concealed. I mention this to account for the non-appearance in the report of any mercurial laxative, which otherwise would have been decidedly indicated. I was induced to put her upon sarsaparilla, with milk, and lime water, from the state of her tongue.

Although stout, the application of the leeches to the os uteri were sufficient to bring on anæmic headache; but as her appetite was good, and she was returning to her home on the coast of Kent, I saw no reason to alter her medicines. I may cite this case as a good illustration of the excellent effects of sea-water taken gradually, and whilst walking about, as mineral waters are. Its action is decidedly more than that of a mere saline laxative; it also possesses alterative qualities to a considerable extent.

Under this treatment the general health improved satisfactorily, the catamenia appeared naturally, and she had no return of the lancinating pains from the time that the leeches were applied. The subsequent gastric derangement was solely the result of her own indiscretion as regards food, and it required several brisk doses of calomel to set her right. The liver was evidently a torpid organ, and prone to congestion, as has since been shown to her cost, she having had since this report two severe attacks of hepatitis, the last of which was during a visit to London, and came under my charge.

Miss W——, ætat. 28. small, dark, sallow.

September 28, 1844.—Complains of constant pain at the orifice of the urethra, sometimes dull, at others sharp, with sensation of dragging, throbbing, tension, swelling, and heat about the part, coming on in paroxysms of flushing, at which times it is so much swollen and gorged with venous congestion, as to be almost livid.

Has pain in the direction of the right kidney, extending to the urethra, increased by pressure or a full bladder; when this latter is much distended, she has a dragging pain about the umbilicus. The dragging pain about the urethra is entirely relieved by lying down. She has no pain on passing water, but leaves off without the sensation of having emptied the bladder. Long standing albuminous leucorrhœa. Severe internal pain in the direction of the os and cervix uteri, much increased by sitting down on a hard seat, or by the passage of solid fæces. Has lancinating pains occasionally in this direction, especially before and at the menstrual period. The catamenia are very irregular, coming at intervals of never more than three weeks, and sometimes only ten days; they are dark, sparing, and sometimes with clots, and the commencement of the period is attended with intense pain, like labour pains. Much hæmorrhoidal congestion; aching limbs; confined bowels. On examination, the orifice of the urethra was found much swollen, forming a soft, vascular and highly sensitive tumour round its edge. I applied some argenti nitr. freely to the part.

℞ Pil. hydrarg., extr. coloc. co., extr. hyoscyami aa. ℈j. M. ft. pil. xij.; sumat ij. om. nocte.

℞. Acid. nitrici dil. tinct. hyosc. aa M. xv., syrupi aurant ʒi. infus. gentianæ co. ℥iss. M. ft. haust. ter die sumend.: lotio plumbi orific. urethræ applicand. Sinapism. epigast. horâ somni.

October 5.—Suffered a good deal from the caustic, but is much relieved since, and has had none of the flushings of heat about the part of which she previously complained, although the sense of dragging at the orifice of the urethra continues. Feels much improved in her general health; the tonic draughts seem to refresh her. Pulse weak; evacuations at first were very unhealthy, but have gradually improved. The leucorrhœa continues. When there is no leucorrhœa, she is tormented with severe internal heat and sense of dryness of the vagina, which she describes to be sometimes as if a large boil were forming there. Expects the catamenia next week.

Hirudines vj. ano. Rep. Medicamenta.

9.—Leeches bled well, with great general as well as local relief. The symptoms of inflammation of the cervix uteri were instantly removed. The tongue is still dry, but the general health is much better. The sallowness of face is greatly diminished. Bowels more healthy.

Rep. Medicamenta.

15.—Catamenia were expected on the 12th, but have not yet appeared; has still a few slight lancinating pains (two or three in a day), and pain on pressing the perineum; there is a slight degree of hæmorrhoidal congestion, and still a feeling of dragging at the umbilicus, and sense of weight about the orificium urethræ; but she can hold and pass her water better. Much tenderness over the right kidney, and corresponding pain on pressure in front, as if the kidney were enlarged. Headache; takes no exercise. Rep. pil. et haustus.

10.—Much better; less bearing down in front, and less pain of perineum; all her other symptoms are better. Has had one or two lancinating pains to-day. The catamenia appeared yesterday morning, preceded by severe pain. The hot semicupium which I had desired her to take on this occasion increased the pelvic pain greatly, but removed it from the lower extremities, and the discharge soon followed. Pergat.

November 1.—No particular change. Bowels slightly confined. Pergat, et sumat confect. sulphuris co. o. m.

8.—The orifice of the urethra is becoming more tender; has still lancinating pains occasionally, and symptoms of prolapsus vesicæ. Much flushing of the vagina. Urine turbid; no pain in the region of the kidney; bowels natural; no throbbing about the anus; has pain only occasionally on sitting down suddenly; little or no leucorrhœa; has neglected the cold sponging and the use of the salt towel which I had recommended. Exam. orificii urethræ:—the swelling has disappeared, and the orifice is nearly natural.

Hirud. vj. ano. Rep. pilulæ.

℞. Liq. potassæ m. x. in decoct. sarsæ co. ter die.

December 5.—Thinks that the mixture did not agree with her. The symptoms connected with the orifice of the urethra have been more troublesome; they fluctuate very suddenly, and at times disappear almost entirely. Has been suffering from lancinating pains, and a good deal of throbbing about the anus. Did not apply the leeches as the catamenia appeared.

Hirudines vj. ano. Rep. pilulæ. Haust acid. nitrici ex infuso gentianæ co. et confect. sulphuris co.

December 13.—Leeches bled moderately, but with great relief. No darting pains, internal flushings, or pain in the direction of right kidney; states that the orifice of the urethra is swollen and tender. Catamenia appeared on the 9th, after an interval of little more than a fortnight, with much pain, but without coagula or previous bearing down.

Rep. haust acidi nitrici c. gentiana.

℞. Ferri sulph. gr. j. extr. gentianæ, extr. hyosc. aa. gr. iv. M. ft. pil. ij. h. s. s. ℞. Sodæ potassio-tart. ʒiss. o. m.

In the absence of any vaginal examination, it might be asked on what grounds have I brought this case under the head of inflammation of the cervix. I would answer, that there were sufficient proofs of its existence, complicated as the case was, to warrant this conclusion. The severe deep-seated pain in the direction of the cervix uteri produced by sitting down suddenly upon a hard seat, and by the passage of solid fæces; the occasional darting pains in the same direction, increased just before and during the menstrual periods, the albuminous leucorrhœa, form a group of symptoms which mark the nature of the complaint.

The swollen, vascular and highly sensitive condition of the orificium urethræ is frequently met with among women, and appears to result from a deranged and irritating state of the urine, in consequence of an early and insidious stage of renal disease. This is certainly the case in some instances, but in others it appears more doubtful. In the present report the pain over the region of the right kidney was well marked. The sense of dragging, which the patient experienced about the urethra, was probably connected with the engorged and therefore heavy, uterus, descending slightly in the pelvis, and thereby putting these parts into a state of painful tension. To the same cause must be attributed some indistinct symptoms of prolapsus of the bladder which existed, such as the dragging pain about the navel, the frequent want to pass water, and the leaving off without the sensation of having emptied the bladder.

The application of lunar caustic to the orificium urethræ was a painful remedy, but it fully answered, and removed the morbid sensibility of the part. The hæmorrhoidal congestion, the long standing, and severe gastro-intestinal derangement, and the vaginal flushing (Nov. 1st), all show a seriously disordered state of the assimilating functions; the irregular condition of the catamenia, both as to time, quantity, and mode of appearance, and the recurrence from time to time of symptoms, indicating the presence of an inflamed cervix uteri, combine to give but an unfavourable prognosis of her future health.

ORIGINAL RESEARCHES ON THE FRONTAL SINUSES, WITH OBSERVATIONS ON THEIR BEARINGS ON THE DOGMAS OF PHRENOLOGY,

By Sir W. Hamilton, Bart., F.R.S.,
Secretary to the Senate of the University of Edinburgh.

II.—Indication of the Sinus.

Fact.—There is no correlation between the extent and existence of a sinus, and the existence and extent of any elevation, whether superciliary or glabellar; either may be present without the other, and when both are co-existent they hold no reciprocal proportion in dimension or figure. Neither is there any form whatever of cranial

development which guarantees either the absence or the presence of a subjacent cavity.

To this fact the phrenologists are unanimous in opposing the following

Fiction.—The sinus, when present, betrays its existence and extent by an irregular elevation of a peculiar character, under the appearance of a bony ridge, or crest, or blister, and is distinguished from the regular forms under which the phrenological organs are developed.

Authorities for the fiction.—It is sufficient to adduce Gall(1) and Spurzheim,(2) followed by Combe,(3) and the phrenologists in general. In support of their position, they adduce no testimony by anatomists, no evidence from nature.

Proof of the fact.—All anatomical authority, as will be seen in the sequel, is opposed to the fiction, for every anatomist concurs in holding that the sinuses are rarely, if ever, absent; whereas, the crests or blisters which the phrenologists regard as an index of these cavities, are of comparatively rare occurrence. It must be admitted, however, that some anatomists have rashly connected the extent of the internal sinus with the extent of the external elevation. The statement of the *fact* is the result of my own observation of above three hundred crania; and any person who would, in like manner, interrogate nature, will find that the largest sinuses are frequently in those foreheads which present no superciliary or glabellar elevations. I may notice, that, of the fifty skulls whose phrenological development was marked under the direction of Spurzheim, and of which a table is appended; the one only head where the frontal sinuses are noted, from the ridge, as present, is the male cranium No. 19,—and that cranium, it will be seen, has sinuses considerably beneath even the average extent.

III.—Frequency of the Sinus.

Fact.—The sinuses are rarely, if ever, wanting in any healthy adult head of either sex.

To this fact, the phrenologists oppose the three following inconsistent fictions:—

Fiction I.—The sinuses are only to be found in some male heads, being frequently absent in men until a pretty advanced age.

Fiction II.—In women, the sinuses are rarely found.

Fiction III.—The presence of the sinus is abnormal; young and adult persons have no cavities between the tables of the frontal bone,—the real frontal sinuses occurring only in old persons, or after chronic insanity.

Authorities for fiction I.—This fiction is held in terms by Gall.(4) The other phrenologists, as we shall see, are much further in the wrong. But even for this fiction they have adduced no testimony of other observers, and detailed no observations of their own.

Proof of the fact, in opposition to this fiction.—All anatomists—there is not a single exception—concur in maintaining a doctrine diametrically opposed to the figment of the phrenologists, that the sinuses are, even in men, frequently or generally absent. Some, however, assert that the sinus in a state of health is *never* wanting; while others insist that though *very rarely*, cases do occur in which it is actually deficient.

Of the *latter* opinion, Fallopius(5) holds that they are present "in all adults," except occasionally in the case of simous foreheads, an exception which Riolanus(6) and others have shown to be false. Shulze,(7) Winslow,(8) Buddeus,(9): "that they are *sometimes* absolutely wanting in cases where the cranium is *spongy* and *honeycombed*." Palfyn,(10): that "they are sometimes, though *rarely* absent." Wittich,(11): "that they are *almost always* present, though it may be admitted, that in *some very rare cases* they are wanting;" and Stalpart Van der Wiel(12) relates, that "he had seen in Nuck's Museum, preserved as a *special rarity*, a cranium without a frontal sinus." Of more recent authorities, Hippolyte Cloquet(13) observes, "that they are *seldom wanting*;" and the present Dr. Monro(14) found, in forty-five skulls, that while three only were without the sinus, in two of them (as observed by Schulze, Winslow, and Buddeus) the cavity had merely been filled up by the deposition of a spongy bone.

Of the *former* opinion, which holds that the sinus is always present, I need only quote, *instar omnium*, the authority of Blumenbach,(15) whose illustrious reputation is in a peculiar manner associated with the anatomy of the human cranium, and who even celebrated his professional inauguration by a dissertation, in some respects the most elaborate we possess, on the Frontal Sinuses themselves. This anatomist cannot be persuaded, even on the observation of Highmore, Albinus, Haller, and the first Monro, that normal cases ever occur of so improbable a defect; "for," he says, "independently of the diseases afterwards to be considered, I can with difficulty admit, that healthy individuals are ever wholly destitute of the frontal sinus; on the contrary, I am convinced, that these distinguished men have not applied the greatest diligence and research." In this opinion, as observed by the present Dr. Monro(16), Blumenbach is supported by the concurrence of Bertin, Portal, Soemmering, Caldani, &c. Nor does the fiction obtain any countenance from the authors whom Blumenbach opposes. I have consulted them, and find that they are all of that class of anatomists who regard the absence of the sinus, though a possible, as a rare and memorable phenomenon. Highmore(17) founds his assertion on the *single* case of a female. Albinus(18) on his own observation, and on that of other anatomists, declares that "the sinuses are *very rarely* absent." The first Monro,(19) speaking of their infinite variety in size and figure, notices as a remarkable occurrence that he had "*even seen cases* in which they were absolutely wanting." And Haller(20) is only able to establish the exception on the case of a *solitary* cranium.

My own experience is soon stated. Having examined above three hundred crania for the purpose of determining this point, I have been unable to find a single skull wholly destitute of a sinus. In crania which were said to be examples of their absence, I found that the sinuses still existed. In some, indeed, I found it only on one side, and in many not ascending to the point of the glabellar region, through which crania are usually cut round. The only instances of its total deficiency are, I believe, those abnormal cases in which, as observed by anatomists, the original cavity has been subsequently occupied by a pumicose deposit. Of this deposit the only examples I met with occurred in males.

Authorities for fiction II.—This fiction also is in terms maintained by Gall.(21) Neither he nor any other phrenologist has adduced any proof of this paradox, nor is there, I believe, to be found a single authority for its support; while its refutation is involved in the refutation already given to fiction I. Nannoni,(22) indeed, says:—"the opinion of Fallopius that the frontal sinuses are often wanting in women, is refuted by observation;" but Fallopius says nothing of the sort. It is also a curious circumstance, that the great majority of cases in which worms, &c., have been found in the sinus, have occurred in females. This is noticed by Salzmann and Honold.(23)

My own observations, extending, as I have remarked, to above three hundred crania, confirms the doctrine of all anatomists, that, in either sex, the absence of this cavity is a rare and abnormal phenomenon, if not an erroneous assertion. I may notice, by the way, the opinion of some anatomists,(24) that the sinuses are smaller in women than in men, seems to be the result of too hasty an induction; and I am inclined to think, from all I have observed, that proportionally to the less size of the female cranium, they will be found equally extensive with the male.

Authorities for fiction III.—This fiction was maintained by Spurzheim while in this country, from one of whose publications(25) it is extracted. It is, perhaps, one of the highest flights of phrenological fancy. Nor has it failed of exciting emulation in the sect. "While a man," says Sir George Mackenzie,(26) "is in the prime of life, and healthy, and manifests the faculties of the frontal organs, such a cavity *very seldom* exists"(!) * * * * "We have examined a GREAT MANY skulls, and *we have not yet seen* ONE having the sinus, that could be proved to have belonged to a person in the vigour of life and mind."(!!) Did Sir George ever see any skull which belonged to any "person in the vigour of life and mind" without a sinus? Did he ever see any adult skull of any person whatever in which such a cavity was not to be found?

Proof of the fact in opposition to this fiction.—This fiction deserves no special answer. It is already more than sufficiently refuted under the first.

It is true, indeed, the doctrine that the frontal sinuses wax large in old age is stated in many anatomical works. I find it as far back as those of Vidus Vidius and Fallopius, but I find no ground for such a statement in nature. This I assert on a comparative examination of some thirty aged skulls. In fact, about the smallest frontal sinus that I ever saw, was in the head of a woman who was accidentally killed in her hundred and first year. (See also the appended table.) I take this indeed for one of the instances in which anatomical authors have blindly copied each other; so that what originates in a blunder or a rash induction, ends in having, to appearance, almost catholic authority in its favour. A curious instance of this sequacity occurs to me. The common fowl has an encephalon, in proportion to its body, about as one to five hundred; that is, it has a brain less, by relation to its body, than almost any other bird or beast. Pozzi (Puteus), in a small table which he published, gave the proportion of the encephalon of the cock to its body, by a blunder, at about half its amount; that is, as one to two hundred and fifty. Haller, copying Pozzi's observation, dropt the cypher, and records in his table, the brain of the common fowl as bearing a proportion to the body of one to twenty-five. This double error was shortly copied by Cuvier, Tiedemann, and, as I have myself noticed, by some twenty other physiologists; so that, at the present moment, to dispute the fact of the common fowl having a brain more than double the size of the human, in proportion to its body, would be to maintain a paradox, counter to the whole stream of scientific authority. The doctrine of the larger the sinus the older the skull, stands, I believe, on no better footing. Indeed, the general opinion, that the brain contracts in the decline of life is, to say the least of it, very doubtful, as I may take another opportunity of showing.

As to the effect of chronic insanity in amplifying the sinuses, I am a sceptic; for I have seen no such effect in the crania of madmen which I have inspected. At all events, admitting the phreno-

logical fancy, it could have no influence on the question, for the statistics of insanity show, that there could not be above one cranium in four hundred where madness could have exerted any effect.

IV.—Extent of the Sinus.

Fact.—While the sinus is always regularly present, it however, varies appreciably in its extent. For whilst, on the average, it affects six or seven organs, it is, however, impossible to determine whether it be confined to one or extended to some seventeen of these.

This fact is counter to three phrenological fictions:

Fiction I.—The frontal sinus is a small cavity.

Fiction II.—The frontal sinus, when present, affects only the organ of locality.

Fiction III.—When the sinus does exist, it only extends an obstacle over two organs (size and lower individuality), or at most, partially affects a third (locality).

Authorities for fiction I.—Mr. Combe(27) maintains this fiction, that the frontal sinus "is a small cavity."

Authorities for fiction II.—Gall(28) contemplates and speaks of the sinus as only affecting locality; and the same may be said of Spurzheim, in his earlier English works.(29)

Authorities for fiction III.—This fiction is that into which Spurzheim modified his previous paradoxes, when in 1825 he published his "Phrenology."(30) Mr. Combe allows that the sinus, in ordinary cases, extends over locality, as well as over size and lower individuality.

All these fictions are, however, sufficiently disproved at once by the following:—

Proof of the fact.—The phrenologists term the sinus (when they allow it being) "*a small cavity.*" Compare this with the description given by impartial anatomists of these caverns. Vidus Vidius (31) characterises them by "spatum *non parvum*;" Banhinus(32) styles them "cavitates *insignes*;" Spigelius, (33) "cavernæ satis *amplæ*;" Laurentius, (34) sinus *amplissimi*;" Bartholinus, (35) "cavitates *amplissimæ*;" Petit, (36) "*grands* cavités irregulieres;" Sabatier, (37) "cavités *larges* et *profondes*;" Soemmering (38) "cava *ampla*;" Monro, (39) primus, "*great* cavities;" and his grandson,(40) *large* cavities."

The phrenologists further assert, that in ordinary cases the frontal sinus covers only two petty organs and a half; that is, extends only a few lines beyond the root of the nose. But what teach the anatomists? "The frontal sinuses," says Portal,(41) "are much more extensive than is generally believed." "*In general,*" says Professor Walther(42) "the sinuses ascend in height nearly to the *middle of the frontal bone.*" Patissier (43) observes, that "their extent varies to infinity, is sometimes stretched upwards to the frontal protuberances, and to the sides, as far as the external orbitar apophyses, as is seen in many crania in the cabinet of the Paris Faculty of Medicine." Bichat (44) delivers the same doctrine nearly in the same words; which, contradicted by none, is maintained by Albinus(45), Haller(46), Buddeus(47), Monro primus(48) and tertius(49), Blumenbach (50), Soemmering(51), Fife(52), Cloquet(53), Volpeau(54)—and, in a word, by every osteologist; for all represent these cavities as endless in their varieties, and extending not unfrequently to the outer angles of the eye-brow, and even to the parietal bones. To finish by a quotation from one of the last and best observers:—"In relation," says Voigtel,(55) "to their abnormal greatness or smallness, the differences, in this respect, whether in one subject as compared with another, or in one sinus in relation to the opposite of the same skull, are of so frequent occurrence, that they vary almost in every crania. They are found so small, that their depth, measured from before backwards, is hardly more than a line; in others, on the contrary, a space of from four, five, to six lines (*i. e.*, half an inch) is found between the anterior and posterior wall. Still more remarkable are the variations of these cavities, in relation to their height, as they frequently rise from the trifling height of four lines to an inch at the glabella." M. Velpeau, speaking of this great and indeterminable extent of the sinus, adds: "this disposition must prevent us from being able to judge of the volume of the anterior parts of the brain by the exterior of the cranium;"—an observation sufficiently obvious in relation to phrenology, and previously made by the present Dr. Monro.(56)

On the sinus and extent, two anatomists only, as far as I am aware, have given an articulate account of their inductions—Schulze and the present Dr. Monro.

The former(57), who wrote a distinct treatise "On the cavities or Sinuses of the Cranial Bones," examined only ten skulls, and does not detail the dimension of each several sinus. After describing these cavities, which he says, "plerisque hominibus formantur," he adds that "when of a middling size they hardly extend towards the temples beyond the centre of the eye, where the orbital vault is highest; and if you measure their height, from the insertion of the nasal bones, you will find it equal to an inch. Such is the condition of this cavity when moderate. That there are sinuses far greater, was taught me by another inspection of a cranium. In this case, the vacuity on the right did not pass the middle of the orbit, but that on the left stretched so far that it only ended over the external angle of the eyebrow, forming a cavity of at least two inches in breadth. Its depth was such as easily to admit the least joint of the middle finger. Its height measured from the root of the nose on the left side exceeded two inches, on the right it was a little less; the left sinus was however shallower than the right. On the left side I have said the cavity terminated over the external angle of the orbit. From this place, a bony wall ran towards the middle of the *crista Galli* and thus separated the sinus into a posterior and an anterior cavity. The posterior extended so far towards the temples, that it reached the place where the frontal and sincipetal bones and the processes of the sphenoidal meet. It covered the whole arch of the orbit, so that all was here seen hollow," &c.

After describing sundry appearances which the sinuses exhibited in another skull, he observes: "It was my fortune to see and to obtain possession of *one* cranium in which of neither of the frontal nor the sphenoidal cavities, was there any vestige whatsoever. In this specimen the bones in which these vacuities are seated were thicker than usual and more cavernous;" an observation as we have seen made by other anatomists. However subversive of the phrenological statement, it will soon be seen that Schulze has understated the usual extent of the impediment.

Dr. Monro (58) after mentioning that there "were forty-five crania of adults in the Anatomical Museum, cut with a view to exhibit the different sizes and forms of the frontal sinuses," says:—"I measured the breadth or distance across the forehead; the height or distance upwards from the transverse suture, where it divides the frontal bones and bones of the nose; and also the depth of the frontal sinuses; in nine different skulls in which these sinuses were large." Omitting the table it is sufficient to say, that in these crania the average is as follows:—*Breadth*, within a trifle of *three inches*; *height*, *one inch and five-tenths*; *depth*, above *one inch*. Here the depth seems not merely the distance between the external and internal tables, but the horizontal distance from the glabella to the posterior wall of the sinus. These nine crania thus yield an average, little larger then an indifferent induction; and though the sinuses are stated to have been large, the skulls appear to have been selected by Dr. Monro, not so much in consequence of that circumstance, as because they were so cut as to afford the means of measuring the cavity in its three dimensions.

PATHOLOGY OF EXPECTORATION.

By S. Wright, M.D., Edin., F.S.A.
Physician to the Birmingham General Dispensary, formerly Senior President of the Royal Medical and Royal Physical Societies of Edinburgh, &c, &c.

Thick mucous sputum. (*a*) *transparent.*—This is a form of expectoration which is often met with in acute diseases of the respiratory organs. Its pathognomonic indications are remarkable for their correctness and constancy.

Appearance and Qualities.—Thick mucous sputum of the transparent kind, differs from ordinary mucus, only in being more dense and tenacious. It is sometimes transparent and glairy, like the white of an egg, and is the "pituita vitrea" of the ancients; in other cases it exhibits a very slight degree of opacity and much frothiness. It is generally tasteless, but occasionally saline. Its usual re-action is neutral or alkaline, but it may be acid. Its specific gravity is, of course, very variable, and is directly as the severity of the inflammatory symptoms which accompany the secretion of this sputum. The tenacity of it is also an exact measure of the amount of inflammatory action. In severe cases it sometimes contains uncoagulated, never solid, albumen; and it never contains pus. Not uncommonly its surface will be finely streaked or dotted with red bright blood, but I believe it is never uniformly tinged, nor rusty-looking. In some cases, it is expectorated with much difficulty, in masses of a semi-globular form, which are scarcely detachable from the sides of the vessel; (1.) in others, it is more easily discharged, more diffluent, and perhaps intermixed with a thinner mucous sputum.

Pathognomonic relations.—The expectoration of the sputum we have just been describing, is always an indication of inflammatory action in the aerial passages. This action is almost invariably confined to the bronchi. I have once or twice remarked this sputum for a few hours after the supervention of pneumonia upon bronchitis, but it quickly passed into the variety which we shall have next to consider. I have never seen it in pneumonia which had not been preceded by bronchitis, and it is rarely distinct when the two diseases are in concert.

(1.) Andral says of this sputum, which is generally attendant upon bronchitis, that, "it does not dissolve in water even by agitation, but remains suspended in the form of long greyish filaments, transparent, and which speedily fall and form a sort of cloud or web at the bottom. Ammonia dissolves this sputum. Sulphuric acid, aided by heat, dissolves and blackens it. At the end of some hours its transparency is restored, and a grumous abundant deposit is found at the bottom of the vessel." *These.*

The commencement of the bronchitic attack is usually attended with a painful dry cough; in a few hours there is a scanty secretion of very tenacious and excessively frothy mucus, having the appearance of white of egg that has been beaten up; this may continue indefinitely, or, as is generally the case, will be succeeded by the sputum of which we are now treating. It is always glairy and tenacious in the direct ratio of the inflammatory symptoms. The frothiness arises from an admixture of air bubbles, derived in the act of respiration and coughing, and is a pretty correct measure of the difficulty with which these functions are performed, and of the quantity and consistency of the mucus contained in the air tubes.

A subsidence of inflammatory action is always denoted when the sputum passes into the opaque variety, or when it acquires a salt taste and an increase of fluidity. And conversely, there is always an aggravation of symptoms in proportion as it returns to its original character and consistence.

The cough, pain, and difficulty of breathing, are generally relieved according to the amount of expectoration, and are augmented in the ratio of its subsidence. Its sudden cessation is an almost certain forerunner of death. In the majority of cases it terminates by passing into the "thin insipid mucous," into the "thick opaque mucous," or into the "saline," sputum. The first is commonly observed amongst young plethoric subjects, the second in the aged or infirm, and the third in people of scrofulous or cachectic habit. But I need not say that these distinctions, though common, are not constant.

Local symptoms and physical signs.—Cough, incessant or intermittent; tickling sensation at the bifurcation of the trachea, aggravated by the recumbent posture; infarction of the chest, dyspnœa, and deep-seated pain behind the sternum, all increased during the act of coughing; heaving respiration; and, perhaps, lividity of the lips, cerebral congestion, intermittent pulse, &c. Percussion often elicits natural sounds, but in severe cases, and in the advanced stage, there is generally more or less dulness in the lower portions of the lungs. When the inflammation is confined to the larger bronchi, auscultation detects a mucous *râle*, gurgling and unequal; and according to the degree and kind of constriction, a sibilant, sonorous, grave or cooing *rale*. In some cases, between constriction and tumefaction, the passage of a bronchus will be obliterated, and in the portion of lung to which it leads, respiration will be inaudible. (2) When the inflammation extends to the smaller bronchi, we have a muco-crepitating *rale*, small and sharp, with incomplete respiratory murmur; and but that the *rale* is slightly liquid and whiffing, that the stroke-sound of the chest is little impaired, and that there is an absence of bronchial respiration, such a case might be easily mistaken for pneumonia. As the sputum becomes purulent, or less viscid, the râle is less intense, and more bubbling; all of which are symptoms of recovery.

Pathology.—The origin of this sputum is essentially inflammatory. The inflammation is of that kind which usually attacks strong, healthy, sanguineous subjects, and which is neither marked nor modified by concurrent disease, nor by constitutional depravity. This sputum, in its pure form, is very rarely met with in the inflammatory affections of scrofulous or cachectic subjects; nor is it usual in the bronchitis which supervenes upon catarrh, fever, or any of the exanthemata. It is chiefly confined to acute, idiopathic, uncomplicated bronchitis. (3)

The morbid appearances vary with the extent and intensity of the inflammation. They chiefly consist of shades of vascularity, from a rosy blush to perfect blackness, either limited or diffused throughout the lining membrane of the bronchi; tumefaction of this membrane, often extending to that of the trachea, and narrowing the aperture of the glottis; more rarely softening or ulceration; constriction, circular or flattened, of the bronchial tubes, which constriction sometimes amounts to obliteration so extensive as to prevent the collapse of the lungs, when the thorax is opened; frothy liquid in the bronchi, in very severe cases tinged with blood, and in unhealthy diatheses, with purulent matter.

Treatment.—The remedial measures employed in these cases should always be prompt and energetic. Bleeding, blistering, mercury, and antimonials, are chiefly to be relied upon, and they must be continued until the character of the expectoration be changed. The glairiness and viscidity of the sputa are unerring guides for our plan of treatment. Active purging, especially with hydragogues, should be avoided. The patient should be kept in an equable and conveniently warm temperature, and, from time to time, should respire the vapour of hot water, containing a little camphor, or other narcotic sedative. This is often of admirable service, in subduing the bronchial inflammation, and diluting the viscid adherent mucus. (4)

Thick Mucous Sputum. *b, opaque.*—This is a form of expectoration which occurs more frequently than any other to the notice of the practitioner. There is scarcely any affection of the respiratory organs, either acute or chronic, which, at some period or other of its course, is not represented by this sputum. And though its services in diagnosis are only of limited availableness or application, it yet deserves a prominent place in the varieties which constitute our tabular arrangement.

Appearances and Qualities.—The characteristics of this sputum are anything but constant. It is sometimes almost semi-transparent, and dotted, streaked, or patched with opaque mucus; and again, its opacity will be perfect, its colour varying from pearly white to every variety of shade of yellow, red, brown, green, blue, and black. In some cases, it is coughed up free of froth, and in masses varying in size from that to a sixpence to that of half-a-crown; these are either distinct or diffluent in the spitting-vessel. The distinct varieties have either ragged or rounded edges. (5) In other cases, it is frothy only on its surface; whilst, in a third instance, it will be frothy throughout, and will not exhibit its accustomed appearance until after rest and exposure. It is usually insipid, but is sometimes nauseous, bitter, sour, or saline. Its ordinary reaction is alkaline, but it may be acid, or neutral. Its range of specific gravity is very considerable, for at one time it is expectorated alone, and in a dense form, (6) and at another, it is discharged floating in a thinner mucus. It consists, for the most part, of mucus,

(2) It has happened that the obliteration of the bronchial passages by this viscid mucus has produced fatal asphyxia. Andral relates a case (*Clin. Med. trans.*, by Spillan, p. 301): "A labourer, fifty-three years of age, entered La Charité in consequence of articular rheumatism: he had also, for about the last two months, an obstinate cough, with expectoration of thick tenacious sputa. The chest, being percussed several times, always yielded a clear sound. The respiration was heard very distinct on all the left side, and with a mixture of mucous *râle* in the upper and middle lobes of the right lung. There was no dyspnœa. He had been already several times bled in consequence of articular inflammation, when, one day, in the midst of a violent fit of coughing, the patient was seized all at once with extreme difficulty of breathing. The remainder of the day, and all the night, there was orthopnœa, and almost continual efforts at coughing. The following morning there was imminent asphyxia, face swollen and violet, extremities livid, pulse nearly extinct. The patient, with difficulty pronouncing some words with panting, intreated that we would relieve him from an enormous weight, which, he said, he felt on a level with his right breast, and which was smothering him. The sonorousness of the chest was not diminished. The respiratory murmur was *puerile* over all the left side; on the right, posteriorly, some mucous *rale* was heard in several points; but on this same side, anteriorly, from the clavicle to a little below the breast, and behind in the supra-spinous fossa, neither the respiration nor the *rale* was heard, though the chest was elevated with force; we supposed there was *pulmonary emphysema.* We had hardly quitted his bed when he expired.—*Post mortem.*—The lungs engorged, as in several dead bodies; presented, however, a tissue which floated in water. Nothing remarkable in the larynx and trachea. We were in total ignorance of the cause of the symptoms, and of death in particular; nothing explained to us the absence of the respiratory murmur recognised during life in the upper part of the right lung, which absence we had referred to emphysema. But on cutting into the bronchi, the blunt point of our scissors met, at the origin of a large air tube, a mass of concrete half-solid mucus, which closed like a stopple this membranous tube, and extended into its interior. It was from this bronchus, thus obliterated, that the branches arose which carried the air into the upper lobe of the lung. The bronchial mucous membrane was also very red." The case immediately following this (*Op. Cit.* p. 302) was one of "chronic bronchitis." The man died suffocated. After death, the bronchi on the left side of the chest were found "livid, red, and filled with puriform mucus. On the right, precisely as in the patient in case II, the principal bronchus, which distributes the air to the upper lobe, was found completely obstructed by tenacious mucus. This mucous concretion extended, like polypous and vascular concretions, into three or four bronchial branches."

(3) This rule, however, is not without its exceptions. I lately attended, in consultation with my friend, Professor Langston Parker, a female, ætat. 39, in whom bronchitis of the severest kind occurred suddenly, as a metastasis of acute rheumatism. I never saw bronchitic sputa more tenacious, transparent, and seemingly characteristic of idiopathic bronchitis. On a re-accession of the rheumatic pains, the cough and expectoration ceased, and the breathing became easy, and marked by only a feeble mucous râle. After the lapse of some hours, the bronchitis recurred suddenly and as severely as before. I am at this time attending an elderly gentleman for an attack of gout. About a fortnight ago, a cessation of the pain in his extremities was followed by pain in his chest, acute mucous and subcrepitant râle, and an expectoration of the purest kind of bronchitic sputa. A dose of Dover's powder at bed-time produced nausea, with profuse spitting, and on the following day, the chest was easy, but the gout had returned to the joints.

(4) The vapour of water in which onions have been boiled is recommended by Dr. Wilson for the same purpose.—(*Treatise on Febrile Diseases*, London, 1803.)

(5) This is the "nummular" sputum of some authors. Louis speaks of it as an almost invariable accompaniment of phthisis. I have watched the career of many a case of phthisis without having observed this variety of expectoration, and again, I have often met with nummular sputum in other than consumptive patients. In some cases, this sputum will acquire the consistence and exact aspect of tolerably thick paste. This form of expectoration was first described by Stoll. It is usually met with in consumptive patients. Doctor Badham says he has met with it in bronchitic affections.—(*Essay on bronchitis.*)

(6) Its density is sometimes extraordinary. Lieutaud speaks of a variety of mucus so hardened as to be almost stony, (Historia Anatomico-Medica. 1767.) I have seen it approach so nearly to solidity as to bear a cutting with a knife, and to preserve distinctly the line and edge of its section. There was no albumen present, and only an average amount of saline and earthy matter. Mucus of this consistence is sometimes expectorated in a perfectly globular form, and of a size varying from a pin's head to a pea. Fourcroy called it *bronchial mucus*; Laennec, from its resemblance to pearls, and to distinguish it from other varieties of pituitous expectoration, denominated it *pearly sputa, sputa margaritacea.* It is generally discharged on rising in a morning, and for an hour afterwards, by dyspeptic and asthmatic people. It often contains fatty matter, and not unfrequently has an excessively offensive odour. In these cases it is yellow and opaque, and resembles the fœtid secretion of the tonsils. It is the chief cause of the matutinal fœtid breath which is common to some subjects, and is only relieved by expectoration.

with a variable proportion of muriate of soda, phosphate of lime, and other salts. It often contains fatty matter, which is separable by ether; blood, bile, and other casual ingredients in indefinite quantity. It is frequently a critical expectoration, and constitutes the *crisis optima* of Stoll.

Pathognomonic relations.—This kind of sputum is common both to acute and chronic affections of the chest. In the former it occurs critically, and is of uniform consistence; in the latter it is discharged casually, and in distinct flattened or globular masses. It is met with as a sequela of acute catarrh, and is sometimes one of the first and most favourable indications of a subsidence of the disease. It often alternates with the thin mucus common to this ailment, and each sputum is a faithful index of the amount of inflammatory action. The glairy viscid mucus of acute bronchitis usually passes into this variety as the patient advances to recovery, of which it is in general a sure sign. In its most transparent and adhesive form it is met with in commencing pneumonia, and is then sometimes so tenacious as to be with considerable difficulty dislodged. I have seen a spitting-vessel containing more than a pint of this sputum, turned upside down, without the contents escaping. Its tenacity is generally in the direct ratio of the amount of inflammatory action. Its degree of transparency is to a less certain extent an index of this action. It is never, however, so transparent as the sputum of bronchitis. In its clearest state it has an appearance like that of horn. It is generally met with, after the commencement of the first stage of pneumonia, of a reddish or rusty hue: this colour, which is due to an intimate admixture of blood derived from the engorged pulmonary vessels, always distinguishes the severer forms of pneumonia. In old subjects, and in very sudden accessions of pulmonary inflammation, this characteristic sputum is sometimes wanting. An uniform red tint is a worse sign than is a partial or patched colouration of the sputum. The pathognomonic indication is good, when the expectoration of the first stage of pneumonia is opaque, with little tenacity, and of a bluish, greenish, or yellowish tinge. As the inflammation subsides, the sputa become more opaque and diffluent, and resemble, to a great extent, those of chronic mucous catarrh. A return of the inflammation is always marked by an increased viscidity of the sputa. As pneumonia advances to the second stage, and even during the period of hepatization, the sputa may either retain the tenacity and rusty tinge of the first stage, (7) or may become thinner and more opaque or may cease altogether. In the third stage, the expectoration, if any there be, is generally very thin and sanious-looking,(8) especially in cachectic subjects; it consists of ill-conditioned mucus, with a little colouring matter of blood, but it rarely contains distinct pus. As pneumonia proceeds towards resolution, the sputa become less bloody, and are, finally, either opaque and pearly-looking, or thin and watery: sometimes these varieties are intermixed. At such time blood itself may be expectorated, alone, or accompanied by other sputum, but the latter is never *uniformly tinged* with blood.

The viscosity and rustiness of sputa of pneumonia, generally occur in their most distinct characters about the second or third day—if later, the indication is favourable. Often, they are evident almost immediately upon the commencement of the attack: this is a bad sign, for under such circumstances the disease rarely terminates by resolution. A sudden and spontaneous cessation of discharge from the lungs, at the height of pneumonia, marks an increase of inflammation which is not likely to be subdued; in the more advanced stages it is a sign of approaching death.

(7) I have repeatedly observed, that how tenacious soever the masses of sputa derived during the second stage of pneumonia may be, *inter se*, yet that they differ from the sputa of the first stage, in adhering little, or not at all to the spitting vessel.

(8) Sometimes they will become suddenly black.

These rules have their exceptions, but they are rare. Andral mentions a case of pneumonia, in which, at the height of the disease, the expectoration suddenly ceased, yet the patient recovered. (9) In other cases, which are very uncommon, the characteristic sputa of the first stage of pneumonia will persist long after the cessation of the crepitating *rale*, and of the other ordinary symptoms of pulmonary inflammation. (10) But we find that the patient either continues stationary or makes very slow advances to recovery; and on listening at his chest, though we may not recognise the distinct crepitation of pneumonia, we detect a sharp muco-crepitating rattle, and an imperfect respiratory murmur, which tell us that the inflammatory action has not yet ceased in the extreme bronchi. In such cases the inflammation readily returns to the parenchyma of the lungs, and the patient generally falls a victim to the relapse. These, and other like facts, indicate how paramountly of consequence it is to regard well the matter of expectoration in pneumonia. Indeed I have more than once experienced the advantage of abiding by the evidence of the sputa, after the failure of all other sources of diagnosis, in detecting and treating obscure inflammation of the lungs. In anomalous cases of pneumonia, expectoration may fail to be present; (11) but being present, it never fails to indicate the amount of inflammatory action.

(9) Recherches sur l' Expectoration dans les differentes maladies de poitrine. Thèse, Paris 1821, p. 35.

(10) Andral gives a case, (Op. Cit. p. 33) in which the viscid expectoration continued for eight or nine days after the disappearance of the crepitating *rale*, and of the other more common signs of pneumonia.

(11) If such cases terminate favourably, the absence of expectoration is generally atoned for by a supplemental action of the kidneys or skin, as observed by Cullen and Frank. I have seen a spontaneous salivation critical of recovery from pneumonia.

OBSERVATIONS ON VARIOUS DEBATABLE QUESTIONS ON THE PRINCIPLES AND PRACTICE OF MIDWIFERY.

By Dr. Clay, Piccadilly, Manchester.

No. V. Second Series.

SUBJECTS: *Remarks on Dr. Churchill—On Irregular Contraction—Ergot not a Cause of Irregular Contractions of the Uterus—Peculiar Action of the Ergot—Effects of Pelvic Pressure—Haste of Practitioners in Hour-Glass Contractions condemned—Cases of Irregular Contraction overcome by Pelvic Pressure—Cases of Irregular Contraction overcome by Ergot—Conclusion.*

In my last remarks, I was about to draw the reader's attention to the chapter on "Irregular Contractions of the Uterus," in Dr. Churchill's excellent volume on "Practical Midwifery;" I there said, the chapter alluded to did not enter so fully or so ably into the question as I was led to expect, from the very able manner in which almost every other part of his work was written. Dr. Churchill states at page 380, edit. 1842, that "irregular contractions of the uterus, after delivery of the child, are *attributed (not without justice, I think,) in some cases, to the action of the ergot of rye.*" Now, with every deference to the worthy author's opinion, I believe practical demonstration will prove the very reverse of the above statement to be the fact. I was one of the earliest in England to introduce the ergot into obstetric practice, *vide London Medical and Physical Journal*, 1823-4, and few practitioners have had as frequent opportunities of testing its utility, and observing the peculiarities of its action, as I have. The whole amount of my experience, then, goes to prove (as well as all I have heard or read, with the above exception) that the action of the ergot is upon the longitudinal fibres of the uterine structure, and the result is, expulsive efforts, more or less strong; on the contrary, irregular action of the uterus after delivery is not with the *longitudinal* fibres, but the *transverse*, and, therefore, to produce the natural action of expulsive efforts, that are at this time called for, it is far more necessary to exhibit the ergot to counterbalance the irregular efforts present, than to attribute to it the cause of irregular action, when I think it can be plainly demonstrated that action is on the opposite series of fibres to those which predominate in all those cases called irregular contractions of the uterus, after the child has been expelled. Again, I believe no axiom in obstetrics is better substantiated than that which states the great majority of cases of irregular contraction after delivery, to be owing to some undue interference, (or what is still more probable, rapid deliveries, in the absence of the medical attendant). Now, if we were to admit the exhibition of the ergot as a cause, it would be at once to admit the presence of the accoucheur, in most cases of irregular contraction, as it is well known the ergot as yet is only exhibited by the medical attendant; when it becomes as common as bohea, we shall, perhaps, hear more of its abuses. I am, however, pretty confident, that we shall not have to class the excitement of the transverse fibres of the uterus among its mal-applications, simply because its influence is over the expulsive fibres, viz. the longitudinal. Accoucheurs know very well, that where *there is expulsive action, it is the height of bad practice to exhibit the ergot at all.* It is only when there are no pains, or very slight transverse pains, *with sufficient dilatation*, that the ergot is justifiable, as a means, to produce what? Expulsive efforts of the longitudinal fibres, over which, from some cause, difficult to explain, the transverse action has predominated, causing a too quiescent state (not paralytic) of the expulsive fibres. The varied forms of irregular contraction, mentioned by authors, are but more or less of the transverse fibres brought into action, and having their action predominating over those of the longitudinal.

It has been my object, in this series of papers, to prove: 1st, the distinct action of the two very different classes of uterine fibres; 2nd, that their exciting causes of action are very different from each other; 3rd, the result of each action differs equally widely; 4th, that either of the classes of fibres excited to undue action is at the expense of the opposite class, robbing the latter of its energies, and causing its fibres to be quiescent, and requiring an extra stimulating power to counteract the irregular, and restore the lost or absent action of the quiescent fibres.

I have also endeavoured to shew: 1st, that a certain degree of tension is the exciting cause of the action of the transverse fibres; 2nd, that pelvic pressure is the exciting cause of action to the longitudinal fibres, producing expulsive efforts, but having no influence whatever over the transverse action; and lastly, that the ergot of rye has not the slightest effect on the dilating process, viz. the transverse, but has a most direct effect on the expulsive efforts of the uterus, and, therefore, it never can be esteemed the cause of an irregular action, over which it has not the slightest control. I shall conclude this division of my subject with a case or two, not the only ones illustrating this latter part of the subject, that have come under my notice, but sufficient to establish the points under consideration. I have often been surprised at the haste exhibited by practitioners to extract the placenta in cases of hour-glass, or irregular contractions of the uterus. There can be nothing to fear from hæmorrhage; the action of the uterus though partial is too energetic for hæmorrhagic discharges, and I have in my recollection a case where the irregular contraction existed for some time, and without any interference of extraction; the character of the pains changed, the longitudinal fibres came into action, and the placenta was expelled by natural efforts. I believe, this would often be the case, if a little more patience were exhibited by the accoucheur. The following case exemplifies the effects of simple pelvic pressure:—Mrs. Jones, Addington-street, in May, 1843, was delivered of a male child about half an hour before I arrived to her assistance; the pains had continued from the birth of the child to be very strong, but were not accompanied with any feeling of bearing downwards, as she had done

when the child was *to be* born. On examination, I found the os uteri, as well as cervix, relaxed, but a decided stricture of the transverse fibres of the uterus, through which the umbilical cord passed. The pains since delivery were strictly characteristic of this irregular contraction; whilst ascertaining the nature of the case, I introduced the whole hand into the vagina (a matter of easy accomplishment after the delivery of the child). My hand introduced, I closed it, and with the fist formed something analogous to a child's head, and with this I pressed gently and steadily upon the inner sacral curve; this manipulation had the immediate effect of producing longitudinal bearing-down pains, and in a few minutes, the placental mass was expelled without the slightest traction of the cord. It is quite evident, if this method was in practice, inversion of the uterus could scarcely ever take place, as it sometimes does, by indiscreet attempts at traction of the cord. It is unnecessary to give more cases on this point, although I have, in my practice, three or four equally satisfactory of pelvic pressure stimulating the dormant longitudinal fibres, and restoring the true natural action of the uterus, as a whole. Before I was sufficiently aware of the beneficial effects of simple pelvic pressure in cases of this description, I had observed, in some half dozen instances, the good effects of the ergot under exactly similar circumstances; it had the effect of restoring the longitudinal action, and of expelling the placenta without having recourse to that violent scheme of boring the hand, in the form of a cone, through the stricture of the uterus, the very act of doing which, tends to excite a greater degree of rigidity in the transverse fibres; so that, in fact, it becomes a trial of strength between the accoucheur and the muscular efforts of a single organ in his patient. Taking the cases of my own practice, and those in the practice of others who have allowed me to suggest the means here laid down, I may, without the least hesitation, state, that I have seen the placenta, or known it to have been expelled in twenty cases that were decided irregularities of contraction, or what is generally called hour-glass contraction, without any traction of the cord, and all the cases would have been deemed such as would require the usual mode of extraction by dilating the stricture. In conclusion, I think the evidence direct as to the ergot of rye and simple pelvic pressure, artificially applied, having the power of stimulating the action of those fibres which are dormant, but which it is necessary to restore before the uterine contents can be expelled. Both these exciting causes act only on the longitudinal fibres,—and I trust I have shewn the uterine action to be in accordance with the practical demonstrations here laid down.

ON UTERINE CONTRACTION, AFTER PARTURITION.

By ROBERT LEWINS, M.D., Fellow of the Royal College of Physicians, Edinburgh, and late Censor, &c. &c.

> At vindicta bonum vita jucundius ipsa,
> Nempe hoc indocti.
> Quippe minuti
> Semper, et infirmi est animi, exiguique voluptas ultio.
> JUVENAL.

Letters have been called the tongue of the world; and science may be regarded in the same light. They supply common objects of interest, in which the selfish unsocial feelings are not called into action, and thus they promote new friendships. Through them, distant people become capable of conversing; and losing by degrees the awkwardness of strangers, and moroseness of suspicion, they learn to know and understand each other. Science the partizan of no country, but the beneficent patroness of all, has liberally opened a temple where all may meet. She never allots a higher or a lower place from exaggerated national claims, or unfounded national antipathies. Her influence on the mind, like that of the sun on the chilled earth, has long been preparing it for higher cultivation, and further improvement. The philosopher of one country should not see an enemy in the philosopher of another: he should take his seat in the temple of science, and ask not who sits beside him.

These generous and harmonizing sentiments, (so diametrically opposed to the feelings of the idle, the ignorant, the envious and vicious members of our profession, and of their aiders and abettors), uttered by Mr. Lawrence, in the theatre of the Royal College of Surgeons, upwards of twenty-five years ago, were brought vividly to my remembrance, by finding myself placed in juxta position with Dr. Clay of Manchester, in the columns of the MEDICAL TIMES, of Saturday last.

In his lucid article, written expressly for the MEDICAL TIMES, entitled Observations on various debateable questions on the principles and practice of midwifery, Dr. Clay has well expounded the laws of uterine action. By his pertinent practical remarks, and simple but expressive diagramatic figures, he has, satisfactorily settled the disputed point, concerning the "hour-glass contraction" of the uterus.

The late Dr. Mackintosh, of Edinburgh, Lecturer on Midwifery, was the first to deny that the form of uterine condition, known by the name of hour-glass contraction, *even* exists—and he continued to do so, until the day of his death. Had the acute and candid physician referred to, lived to read Dr. Clay's paper, he would, I am convinced, have altered, or modified his opinion. Dr. Mackintosh maintained, that what has been called hour glass contraction of the uterus is merely a premature spasmodic action of the cervix and os uteri, before the expulsion of the partially detached placenta—and that accoucheurs mistake the diminished uterine aperture for a spasmodic state of the body of the womb—conceiving the upper part of the vagina to be the lower compartment of the uterus! a mistake, undoubtedly, sometimes committed.

It is quite evident that the views and opinions of Dr. Mackintosh were consistent with, and corroborative of, the reasoning of Dr. Clay.

Tiverton, Devonshire, May 20, 1845.

POISONING BY FISH.

To the Editor of the "Medical Times."

SIR,—Desirous of encouraging the investigation of that department of Toxicology, which treats of the morbid effects resulting from the contact or sting of several individuals of the fish species, I transmit the following case for your perusal, (and should you consider it worthy of publication) for a portion of your valued Journal.

It may be said that as a case it only forms one of that numerous family which contribute to perplex the student and encumber medecine with anomaly. But where inquiry is stagnant and requires the stimulation that such cases as the following are calculated to produce, I may be excused for its contribution, when its subject is allowed to be involved in neglect or obscurity.

Early in the year 1844, I was engaged in the performance of duties as surgeon of an East Indiaman then at anchor in Port Louis, Mauritius, and during the prevalence of weather that indicated an approaching hurricane. The morning was usually characterized by the serenity and beauty of a tropical sky, but as evening approached, the weather rapidly assumed the boisterous nature peculiar to the monsoon. The rain fell in torrents, and the wind suddenly rose and continued with unabated fury, until the hour arrived when its violence was exchanged for a sultry and oppressive night.

It was during one of those evenings when the storm had been unusually brief in its duration that a considerable portion of the ship's company were permitted by the chief-mate in charge of the boat, to proceed to a distant and more inviting situation than the harbour afforded, for the purpose of bathing. Such a spot was soon selected, but as soon relinquished, when the mate after his first plunge regained the shore with difficulty, and complained of a most acute and stinging sensation in the thumb of the left hand. The men lost no time in returning with their officer to the ship, and I had therefore an opportunity of seeing him soon after the infliction of the wound. His countenance, always the index of rude and vigorous health attracted my early attention, as he was now pale and anxious, and presented rather the indications of excessive pain than those of fear. Although his constitution was hitherto perhaps a stranger to the invasion of disease, it was ill fitted to resist the more severe effects of morbid poison. Highly sanguineous and plethoric, he early manifested the symptoms of its rapid diffusion. On examination, I found the wounds were minute and punctured, on the distal palmar surface of the thumb, and in regular order. To these I applied nitrate of silver, but with no relief to the acute pain of which he complained. The patient, however, was not long in bed before the brain partook of the general disturbance. The skin became hot and febrile, and the pulse was quick and small. The arm now rapidly tumefied, and the course of the lymphatics was distinct and defined; I scarified the arm and fore-arm very freely, and by means of the cupping glasses obtained a considerable quantity of blood, directing the administration at the same time of pills containing camphor and opium, and it was not until a decided impression had been made on the circulation by the depletion, that the functions of the brain regained their healthy action, as the restlessness, apprehension, and incoherence of the patient had hitherto been constant and urgent. The bleeding was encouraged by hot fomentations and poultices, which were repeated, and continued for several days, but were subsequently replaced by cold evaporating lotions.

It is unnecessary to be more diffuse in the details of treatment, as its success was attributable to the early use of depletory measures, and was latterly devoted to the relief of small abscesses, occurring on the arm, and to the restoration of freedom in the use of the thumb, which from long disuse, had become weak and wasted. The weakness was overcome, but the difference in the size of the thumbs remained apparent, and unaltered.

The information which I endeavoured to obtain from residents on the Island, with reference to this poison was unsatisfactory, as I understood that the victims of similar accidents, were to be found chiefly among the humbler class of natives, who possessing and applying their own peculiar remedies, seldom resorted to Europeans for advice or assistance. The fish is known to the Creoles, as the Laffe, and although I had no opportunity of seeing or procuring a specimen, I am induced to present this instance of the danger attending its attack to your attention, from the importance which such cases assume, when plethoric and susceptible individuals are their subjects.

I am Sir, &c.,

VANS. C. CLARKE, M.D., R.N.,
H.M.S. "Daring."

Plymouth Sound.

PROGRESS OF FRENCH SCIENCE.

FROM OUR OWN CORRESPONDENT.

Paris, May 22, 1845

Orchitis.—In two of my former letters (vide *Medical Times*, Vol. X. p. 493., and Vol. XI. p. 59.). I mentioned the method which has been successfully adopted by Dr. Vidal de Cassis in the treatment of this affection; in the present article I purpose relating two cases which occurred in the practice of Professor Velpeau at La Charité, and describing the mode of treatment adopted by this distinguished surgeon. John Dangle, servant, ætat. 23, in general enjoys good health, strong constitution; the disease commenced eight days before his admission into the hospital, but was relieved by the use of a suspensory bandage; in consequence, however, of the imprudence of the patient, who walked about a great deal, the swelling increased, and was accompanied by insomnia, constipation, vomiting from time to time, and very painful erections. These symptoms increasing in intensity, the patient was admitted into La Charité on the 25th of June, 1844; he then presented the following symptoms:—discharge *per urethram*, mucous rather than purulent, which the patient affirms to have appeared only the day before; no pain in the canal, no scalding while passing the urine, which flows as easily as before the attack; pain in the groin very slight in the recumbent, more so in the erect position; glands

neither tumefied nor painful; skin of the scrotum red, not very tense; veins not swollen; no infiltration in the envelopes of the scrotum; pasty feel of the parts; tunica vaginalis distended with liquid; as to the tumour formed by the testicle it is impossible to ascertain its exact size, nor whether the swelling is seated in the testicle or epididymis, but, in all probability, it is the former, as the most painful part is the antero-inferior, and as the spermatic cord is not in the least so, even when touched. Three punctures were made with a lancet; about a table spoonful of bloody serum escaped; the tumour, however, did not diminish much in volume. Cataplasms moistened with the liq. plumb. acet. were ordered to be kept constantly applied to the part.—25th. Swelling diminished one third, heat and redness less; not so painful on pressure, nor so hard; discharge *per urethram* ceased; slight pain at the meatus urinarius immediately after micturition. Contin. catapl. cum liq. plumb. acet.—26th. Pressure no longer painful; heat and redness nearly disappeared; volume considerably diminished—compresses wet with Goulard water to be kept on the part.—27th. The improvement continues, but as the tunica vaginalis still contains a small quantity of liquid, two punctures were made with a lancet, and a small quantity of sanguinolent serosity escaped. Cataplas. cum liq. plumb. acet.—28th. Improvement continues. Goulard water.—29th. All the inflammatory symptoms have disappeared; there remains only a slight tumefaction, which is not painful when touched; no discharge.—July 1st. The right testicle is still somewhat larger than its fellow, and has slight elevations on its surface. Though not quite recovered, he left the hospital. *Remarks.*—The patient declared that the orchitis preceded the gonorrhœa; although not probable, still it is not impossible; orchitis supervenes when the inflammation has reached the prostatic region; now this takes place generally at an advanced stage of gonorrhœa, but if the disease commenced near the prostate, owing to excess of venery, it might extend itself immediately to the testicle. Case 2nd.—Edward M——, aged 29, tailor, general health good; about four years ago was affected with chancres, which were methodically treated by Dr. Ricord; since that period he contracted gonorrhœa twice, of which he asserted he was cured before the attack which brought him to the hospital; he also suffered a year ago from orchitis on the right side, which continued twenty days, and was successfully treated at la Pitié.—July 11th. On admission, there was a tumour on the right side of the scrotum 3¾ inches in height, and 6½ inches in circumference transversely, of a brighter red than the opposite side, not painful, nor very hard anteriorly, but very much so posteriorly, the hardness extending upwards in the spermatic cord for about three inches; epididymis very hard, not very painful on pressure, in fact, the only part which was painful was anteriorly and inferiorly; no œdema of the envelopes; the swelling commenced a fortnight ago, was very painful, but by means of emollient cataplasms diminished to one half its original size; he had a mucous discharge *per urethram*, but referred the attack to considerable bodily fatigue. The part was punctured with a lancet, which allowed about a table-spoonful of liquid to escape. Catapl. cum liq. plumb. acet.—12th. Hardness still in the cord and epididymis; diminution in size; symptoms less severe. Goulard water.—13th. Continues to improve; no pain, even on pressure; cord and epididymis in the same state. Goulard water. ℞. Ol. ricini ℥iss.—14th to 17th. No change.—18th. Epididymis somewhat harder; general aspect satisfactory; a second puncture was made in the scrotum, which allowed a small quantity of reddish serosity to escape. Frictions with the ung. hydrargyri fortius on the cord.—19th. The patient left the hospital not quite cured, inasmuch as the epididymis and spermatic cord continued hard; in general, when orchitis is complicated with great hardness in the cord, it seldom can be cured by punctures, because the phlegmasia has proceeded too far.

Abscesses in Various Parts of the Body Consecutive to Labour.—D——, ætat. 34; was confined on the 10th February at the Lying-in Hospital; immediately after which she was affected with colic and diarrhœa, and some days after with violent pain and swelling at the posterior and inferior portion of the left leg, and with indolent tumours on the outer side of the fore-arms; the patient left the Maternité on the 24th and returned home, but as she continued to suffer from considerable pain and swelling in the right hand, she came to Necker Hospital, and was admitted into Professor Trousseau's wards on the 25th February.—The right hand and part of the fore-arm were tumefied, red, painful, and œdematous; the small tumours already mentioned, were red and indolent, and presented evident fluctuation; when opened with a lancet, healthy pus escaped; posteriorly on the left leg from about the middle of the calf to the malleoli there was a painful red pasty tumour uncomplicated with œdema of the foot or leg; superficial veins swollen; not much fever; abdomen not painful; suppression of the lochia; tongue moist, foul; anorexia; thirst; abundant diarrhœa:—℞. pulv. ipecac. ℈ij. statim sumend.—28th. Vomited frequently; hand not quite so swollen; other symptoms *ut antea.*—1st May. Tumefaction and redness of the fore-arm increased; fluctuation could be felt in two spots; opened on the 2nd; about a tablespoonful of pus escaped.—4th. Fever and diarrhœa still continue; the tumour of the left leg presented evident fluctuation, and an opening having been made, a considerable quantity of serous pus escaped, its discharge being facilitated by pressure on the calf of the leg.—℞ Hydrargyri protochlor.; gr. x.; opii gr. i. M. pulv. statim sumend. —5th. The patient complained of pain in the muscles of the fore-arm, and on examination a small tumour was perceptible; fever not very great; two copious stools; thirst not so intense;—6th. Same state: abundant suppuration from the abscess on the leg; fluctuation was evident at the upper and inner part of the fore-arm;—10th. Several abscesses similar to those already described at the lower part of the arm, which were opened successively, soon healed up.—17th. No new formation of abscess; she labours now only under weakness; after remaining some time longer to recover her strength, the patient finally left the hospital quite well.

On Diseases of the Eye.—By Professor Velpeau, (continued.) The symptoms enumerated in the preceding lecture are sufficient to enable the practitioner to recognize iritis in the first stage. But as the disease advances, certain modifications in the existing, or new, symptoms may be observed, and these are so important as to be worthy our most serious attention. Thus, when the inflammation has existed four or five days, the cephalalgia may have become very intense, so much so as to cause in some cases continual insomnia, in others on the contrary it acts on the digestive organs, disturbing their functions and producing a dislike for food, anorexia, nausea and foul tongue, and on the circulation, giving rise to fever. These symptoms are highly important, inasmuch as it is only in inflammation of the globe of the eye or in iritis that they are observed; for, as was already stated when describing blepharitis, conjunctivitis, and keratitis, no fever exists. Finally, the cephalalgia may affect only one side of the head, and may assume a neuralgic form.

2nd stage.—Photophobia and epiphora unchanged; colour of the iris presents various tints; for instance, when naturally blue it becomes of a reddish brown; when grey, dark grey; when black or brown, it assumes a velvety aspect and a darker hue: in fact, it may be asserted that when in this disease the iris changes its colour, it becomes of a deeper hue than in its normal state. In some cases, small vessels, which are not visible in the healthy condition, become apparent, that is, there is a vascular injection of the iris. While speaking of keratitis, this symptom was said to be sometimes present, and its existence in iritis is more readily conceived, inasmuch as the iris is far more vascular than the cornea. The surface of the iris presents a velvety, thickened appearance as if fungous; small tumours are sometimes visible in its parenchyma, produced by effusions of various kinds, of blood, pus, or plastic lymph. However extraordinary this fact may appear, still it is no less true, and I have seen two, three, four, and even five such tumours in the same individual simultaneously; in general they are situated on the margins of the iris. In a patient now in my wards there is a tumour near the outer margin, which appears to be formed by an effusion of blood; in another, there is, near the larger circumference also, an abscess about the size of a hemp-seed. It is, therefore, certain that one or more effusions and abscesses may take place in the iris in this stage, not in the former, for reasons too easily understood to need explanation. When the disease has lasted some time, different changes are perceived in the pupil; thus its mobility is diminished or lost; it becomes smaller, or is closed altogether, producing what is is called *synizesis* or *phthisis pupillæ*; the iris may also contract adhesions by its anterior or posterior surface, *synechia anterior* or *posterior*. These different phenomena are easily explained, on reflecting on what occurs, when the iris is inflamed. Thus the membrane will be pushed backwards or forwards, according as the effusion caused by the inflammation is greater anteriorly or posteriorly, in the camera anterior or posterior. When this phlegmasia is more intense on the anterior face of the iris, the aqueous humour increasing in quantity will produce synechia posterior, on the contrary, if the uveal aspect is the seat of the affection, synechia anterior may be the result. There appear likewise in this stage, other phenomena, as sequelæ to the inflammation; thus, pseudo-membranes may be formed in the pupil, sometimes like a net-work, at others like a cloud or white, yellowish, milky, or reddish spots. These results are by far the most serious, for it is by them defective vision is caused, and even blindness. The various complications are also far more frequent in this period; such as inflammation of the membrane of the aqueous humour, deep seated keratitis; small spots deeply situated as if in a cloud, or just before the capsule of the crystalline lens; they are formed by the organic lamellæ situated near the phlegmasia, which are slightly inflamed. Iritis may exist alone for eight or ten days, after which it is generally sooner or later complicated with inflammation of the other membranes of the eye. Another sign, which does not exist in the other diseases which have been examined hitherto is here met with; it is a peculiar brilliancy of the surface of the eye, owing probably to the super-secretion of tears, and at the same time a perfect transparency of the membranes. Something analogous may be observed in keratitis, but it is then accompanied by a greenish, or water-green tint, whereas in iritis, with the brilliant aspect, the eye retains its normal colour. The patient complains of a feeling of fulness, as if the eye were compressed, this sensation being caused by the over-distension of the organ; the mode in which this is produced is similar to that observed, when a ring put on a finger, causes the portion situated below it to swell by its constriction: the sensation is evidently the same, though the causes are very different. In iritis there is an increase of the fluids of the eye—aqueous humour, vitreous humour, &c.—which, owing to the resistance presented by the sclerotica to its distension, produces a painful sensation. The mode in which the pain is caused may be explained by the distension of the sclerotic coat, and the pressure from within outwards by the humours on the retina, choroid, sclerotica, and the nerves situated between them; the more so, as it is in direct proportion to the inflammation and therefore to the quantity of liquid effused, and may irradiate towards the sub-orbitar region, following the ramifications of the nerves. The pain in iritis affects principally the forehead, temples, and brain by sympathy, whereas in keratitis, the mucous membrane of the nose and corresponding maxillary sinus, is usually acted upon. Finally, iritis may be accompanied, as before stated, by disorder of the functions of the digestive organs.

In the next lecture the differential diagnosis between simple and specific iritis will be examined.

On Hydrarthrosis.—In a preceding letter (vide *Medical Times*, Vol. IX., p. 402,) the mode of treatment adopted by Dr. Gimelle in this affection, was made known; in the four following cases, observed in the wards of Dr. Malgaigne, at the Hospital St. Antoine, it was successful in one instance,

whilst in the rest, other remedies proved equally efcacious. Case 1st.—A sawyer, ætat 43, was brought to the hospital on the 21st of Feb., on account of a violent contusion of the left leg, caused by a blow from a beam while at work. The inflammation which followed the accident, continued during eight days, and the swelling was so considerable as to lead to the supposition that phlegmonous suppuration had taken place, were it not that throbbing pain and shiverings did not exist. All at once, on the 1st of March, the symptoms of hydrarthrosis in the knee set in, and at the same time all the untoward signs in the leg disappeared. Two days after, there existed considerable effusion in the articulation; tartar emetic was in consequence prescribed in the dose of gr. vj., which was increased gr. ij. daily, until grs. xiv. were administered; this dose was given for three days, and then gradually diminished, and finally, four days after was omitted altogether, the effusion at this period having been absorbed so that the circumference of the knee was only a line more than that of the opposite one. The remaining enlargement disappeared completely on the patient's getting up and walking about. The tartar emetic produced the first two or three days abundant vomiting and stools, which ceased after some time, though the dose was increased. Case 2nd.—N——, ætat. 17, printer, was seized, without any appreciable cause, with tumefaction of the right knee; no pain; movements of the limb difficult; fluctuation; semi-flexion; circumference of the knee an inch and a half larger than its fellow. Tartar emetic having been administered as in the preceding case, for thirteen days, without producing any beneficial effect, the following treatment was adopted:—a large blister was applied on the knee, and a second a few days after, followed by emollient cataplasms on the denuded surface. On the sixth day, the blisters being healed, the knee was measured and found to have diminished nearly an inch, and two days after the patient left the hospital quite well. Case 3rd.—J. ætat. 48, after the consolidation of a fracture of the leg was affected with hydrarthrosis, in all probability owing to a slight degree of irritation produced by the motion necessary to overcome the stiffness of the joint. Two temporary blisters were sufficient to cause the absorption of the effused fluid. Case 4th.—As in the preceding, the affection was here produced by the movements necessary to over come the stiffness of the joint, consecutive to a fracture of the lower third of the femur in an old man, seventy years of age, the apparatus having been kept on the limb for fifty-eight days. There was great pain on the least movement; the circumference of the articulation had increased about two inches; pulse hard and frequent; twelve ounces of blood were drawn from the arm, and emollient cataplasms and baths were had recourse to, under which treatment the patient soon recovered.—*Gaz. des Hopitaux.*

Academy of Sciences. Sitting of the 19th of May, M. Elie de Beaumont in the chair.—Received, "Calcutta Journal of Natural History," edited under the superintendence of Mr John M'Clelland, Bengal Medical Service, for Geology, and Zoology, and of Mr. W. Griffith, F.L.S., Madras Medical Service, for Botany, Nos. 17, 18, 19, 20. April, July, October, 1844, and Jan. 1845.

On a Parasite of the Ear, by M. L. Berger. The author considers as erroneous the opinion generally admitted in physiology, that the cerumen is intended by nature to prevent insects entering that organ, since he discovered in the ear an animalcule of the genus *Tardigrade,* whose dimensions are enormous compared to the other *infusoria* of the human body. After giving a minute description of this animalcule—which is a species of elongated worm—the author concludes by stating that he has also discovered its larvæ.

On the Manner in which Animal Diastasis acts on Fæcula, by M. Mialhe. The author, in reply in M. Lassaigne, after quoting several passages of his preceding memoir, concludes—1°. That uncooked as well as cooked fecula, may be rendered soluble and capable of assimilation by means of animal diastasis.—2°. That without the presence of animal diastasis, fæcula would never be absorbed, as was proved by the interesting experiments performed by M. Payen on plants.

On Deafness.—M. Pappenheim writes to rectify some errors in his memoir presented at a late sitting.—1°. That chloresterine was found in the internal and middle ear, not as the result of catheterism, but of typhoid fever.—2°. That it is not the existence (as it is always present), but the abnormal increase of carbonate of lime in the internal ear, which causes deafness.

On the Epidemics reputed by turns Contagious or non-contagious, by Dr. Hombron.—Epidemics form a class of diseases to which the denomination of pestis may be given, because it really is their origin; they may be divided into two classes—1°. The affections caused by external infection, at first local, and propagated by inoculation.—2°. Affections by internal infection, or general from the commencement, and propagated by means of the respiration and cutaneous absorption; variola is the connecting link between the first and second. The latter may be subdivided into—(*A*), those poisoning by miasmata—(*a*), variola and its varieties—(*b*), rubeola, scarlatina, and their varieties—(*B*), those poisoning by effluvia—(*a*), typhus of Europe or of the Levant—(*b*), typhoid fever and its varieties. Finally, the author, from the comparative study of various epidemics concludes, that their origin and mode of development are almost identical; that if one which presents no pathological excretion is contagious, all those similarly situated must be so likewise, but that contagion here is an hypothesis—that quarantines being useless, are necessarily injurious—that like scurvy, the yellow fever is not contagious, and cannot be considered as a species of typhus.

On the Physiological Phenomena Observed whilst Ascending Mountains.—By Dr. Castel, M.A.M. The physiological phenomena remarked by travellers when ascending mountains are produced by the diminution of atmospheric pressure, not because this diminution, as some authors have asserted, increases the rapidity of the circulation in the small arteries and veins, but because it exercises a direct and constant influence on the contractility, to which the circulation is always more or less subjected. A modification in the one must of necessity be followed by an anomaly in the other. Contractility is more and more diminished as the atmospheric pressure becomes less, and it is in considering the subject in this light that the phenomena mentioned by M. de Pileur in a memoir presented at a late sitting, can be satisfactorily explained. There is not one which can not be attributed to the disturbance of the circulation; this disturbance in its appearance and progress is in proportion to the rarefaction of the air. Thus at a height of from 9850 to 11,590 feet above the level of the sea, the travellers experience, fatigue, vertigo, nausea, evident signs of commencing atony;—from 11,590 to 13,200 feet, dyspnœa, somnolence, colics, faintings, syncope, produced evidently by the dilatation of the vascular extremities owing to the blood not circulating, and afterwards by pressure on a portion of the nervous system—from 13,200 to 15,000 feet, anhelatio, faintness, pain and extreme weariness in the limbs. Why? because the distension of the vessels is carried beyond all limits, and anhelatio is the most prominent symptom, the respiratory organs being the most vascular. The loss of power in the muscular system is a proof of the diminution of the contractility, and is it not from a similar cause that the loss of muscular power in several varieties of fever constitutes one of the most dangerous symptoms? Finally at 16,500, the dilatation of the vessels and the sluggishness of the circulation extend to the venous trunks, and even to the heart; here in addition to the phenomena already enumerated are remarked, palpitations; pulse accelerated, and frequent in a direct ratio with its feebleness, as is sometimes observed just before the fatal moment; distension of the vessels, and the absence of all restraint often causes the rupture not only of the extremities of the arteries, but also of the larger vessels, as in the case recorded some years ago in the *Journal des Savans,* of M. Plantade, *Ingenieur Geographe,* who died from hæmorrhage on the summit of the Pyrenees. It is well known that elevated sites do not agree with weak-chested individuals. The same causes may produce apoplexy, for are not the vessels of the brain, like those of the other cavities, subjected to dilatation and obstruction owing to the rarefaction of the air? Is it necessary to add that this is according to the elevation, and *vice versa*? M. Amontons has demonstrated by precise calculation that if a column of air could be increased *ad libitum,* its lowest layers would present the density of mercury. According to the relation of density and pressure, nature has established differences in the volume and power of the respiratory and circulatory apparatus in the different classes of the animal kingdom. Thus in birds the volume of the heart with respect to the size of the body, is as 1·168—in quadrupeds, it is as 1·263—and in fishes as 1·1360; consider now what is the respective density of the various media in which these animals live, and the influence they exercise on the contractility which, it may be added, is the primum mobile of all our functions.

These are the means by which physiology ought to explain the phenomena experienced when ascending mountains. The causes are uniform, differing only by the degree of intensity; thus the distinction proposed by M. Le Pileur, with respect to the rarefaction of the atmosphere and muscular motion, is, in my opinion, not founded; for, if they act with greater violence on persons on foot than on those on horseback, it is because in the latter the greater part of the muscles are inactive, whilst in the former they are constantly in motion.

On the Ioway Indians, by M. Jacquinot. According to the author, North and South America were peopled by the same race of men, whose various colonies, issuing from the same stock, present the same anthropological characters, and differ only by very slight shades, which far from constituting marked races or species, present only the slight individualities generally met with in all the nations proceeding from the same parent stock. The Esquimaux and some of the black tribes of California, may, perhaps, form an exception, as, according to some travellers, they present marked differences; this fact deserves confirmation. But independently of the analogy which exists between the inhabitants of north and south America, they have likewise a striking resemblance with the inhabitants of distant parts; for instance with the Polynesian islands. This observation (which the author thinks has never yet been announced) is not grounded on some distant relations, on some analogy in the manners, customs, and language; but on the most exact resemblance in the features, in short in all the physical characters.

On the utility of the diapason in deafness, by Dr. Bonnafont. From his experiments the author ascertained, that when in any given part of the cranium a certain note could not be heard, the lower ones could be distinctly perceived—that in proportion as the sensibility diminishes, the ear loses the faculty of hearing a high note, whilst it retains that of perceiving the lower ones—that whenever the sensibility of the acoustic nerve is diminished, deafness commenced by the higher notes, the ear losing more and more the power of perceiving the lower ones as its sensibility decreased—that it was by means of this method, that the various degrees of deafness and incurable cases were discovered.

Academy of Medicine.—Sitting of 20th May.—M. Caventou in the chair.

Nomination of Dr. Longet.—Dr. Pariset, perpetual secretary, read the ordonnance of his Majesty, confirming the nomination of Dr. Longet as member of the Academy.

Incident relative to Dr. Fontan's memoir on the mineral waters of Bagneres de Luchon. Dr. Gerardin.—In requesting to be heard, I wish to be understood that my demand has nothing exceptional; it is spontaneous, and free from all foreign influence. In the last sitting, while speaking of mineral waters in general, I spoke against the mercenary system, which has, of late, been introduced into the different establishments, which to attain their end, sacrifice the interests of medicine, the dignity of our art, and the respect due to the Academy. With respect to the memoir read on the waters of Bagneres de Luchon, I blamed the mode in which the facts were brought forward, and in this respect, I made use of my right as a member of the Academy. It would seem that my words were interpreted very differently, and raised feelings which I did my best to allay. In this

of the question, I now declare that the words I uttered, and which I do not retract, had nothing personal, and in making this declaration, I wish it to be perfectly understood, that I do it of my own free will. Dr. Dubois d'Amiens.—I will add that in the preceding sitting, the president stated to Dr. Fontan, that such was Dr. Gerardin's meaning. Dr. Louis.—I am happy to hear the explanations given by Dr. G., the more so as I am intimately acquainted with Dr. Fontan: none of the remarks were applicable to him, who is one of the worthiest persons I know, and whose scruples in a scientific point of view are carried to the extreme.

On Secret Remedies.—M. Boudet read several official reports on this subject. Conclusions. None worthy of approval (adopted.)

Artificial Anatomy.—Professor A. Berard read a report on the anatomical preparations in leather, presented by M.M. Cartaux and Chailloux. These preparations are very advantageous, on account of the resemblance they have to the parts they represent, their solidity, and the length of time they last, are superior to all hitherto invented, and consequently are deserving of the Academy. M. Bussy asked what colouring matter was employed, whether mineral or vegetable? The conclusions are postponed until the sitting, in order to enable M.M. Cartaux and Chailloux, to place specimens before the Academy.

On the Contagion of Typhoid Fever.—Dr. Bricheteau read a report on a memoir presented by Dr. Patry, (Indre et Loire,) who considers typhoid fever as contagious, and quotes several cases in support of this opinion. After giving an analysis of the memoir, the reporter states, that he agrees with Dr. P. as far as small localities are concerned, and if such is not the case in large cities and hospitals, it is because the rules of hygiene are more strictly attended to; that the uncleanliness and carelessness of the peasantry are causes sufficient to account for its propagation by contagion, although the disease originates in infection. *Conclusions.*—Thanks to the author; request that he should continue to pursue his interesting researches; and to place his name on the list of future correspondents. Professor Moreau.—I agree with the author, and consequently differ in opinion with the learned reporter. I do not think typhoid fever contagious by infection, but *per se*; and among the numerous facts on which this opinion is founded, the following may be quoted. The daughter of a farmer in easy circumstances, residing eighteen miles from Paris, fell ill of typhoid fever, and died on the 21st day, in spite of the utmost care and attention. Her brother, a robust young man, 24 years old, who resided at a neighbouring farm, came to see his sister, and finding her so ill, refused to leave her. Two days after the funeral, on his return home, he was in his turn affected, and eight days after, was no more. The mother who had attended the two during their illness, fell sick likewise, on the fourth day after the death of her son, and the disorder terminated fatally on the tenth. Medical care was not wanting here, for not only the physicians of the place were in constant attendance, but also Professor Chomel and myself saw the patient several times. Here the disease was evidently propagated by contagion, not infection. Dr. Bricheteau in reply, stated, that his opinion was not so much at variance with that of Professor Moreau as he imagined; since he (Dr. B.) thought that there is first contagion, and then infection. Dr. Rochoux.—I do not think that the diseases of small localities differ from those observed in large cities; the dothinenteritis seen in the former, is in every respect similar to that of the latter. If, however, it is contagious in one, and not in the other, it is evidently not the same affection. What is supposed to be contagious dothinenteritis, is not this disorder, but typhus; the more so, as for the last thirty years, there has not been one authentic case of dothinenteritis propagated in Paris by contagion. A disease cannot be contagious or non-contagious according as it affects the inhabitants of a village, a small town, or a large city, and, in all probability, it was typhus, not typhoid fever, which was observed by the author of the memoir. The following fact comes in support of this opinion: in 1813, a patient affected with typhus, was received in the *Maison Royale de Santé*, and communicated it to four individuals; two of them died; at the same time, several hundred persons suffering from typhoid fever were likewise received, and notwithstanding that large number, the disease was not propagated in the establishment. Dr. Bricheteau differed in opinion from Dr. Rochoux as to the impossibility of there being a dissimilitude between the same diseases when observed in the country, in small towns, or in large cities, like Paris. As to the disease under consideration, it was evidently a dothinenteritis, as any one may be convinced on reading the description given by the author, and there is no reason why it should not be contagious, according to the localities. Dr. Collineau has had repeated opportunities of observing typhoid fever in Paris, and in the country, and never saw any difference in the symptoms: as to contagion, he never observed it in Paris; whilst country practititioners affirm that it frequently occurs. Dr. Castel.—No disease can be said to be propagated solely by contagion, as this depends on accessory phenomena, which do not constitute a disease. It would indeed be far better were both terms struck out of medical works. The propagation of a malady depends more on its duration, than on its nature, besides which, other causes exist, such as want, uncleanliness, influence of climate, season, &c., so that an affection which is not contagious in one instance, or clime, may become so in another. Contagion ought, therefore, only to be considered as an epiphenomenon. Dr. Rochoux.—In my opinion, contagion forms the fundamental character of certain diseases; variola, syphilis, hydrophobia, &c., but is it the same with dothinenteritis? Evidently not, for as I have already stated, there has not been one authentic case occurring in Paris, for the last thirty years. Dr. Gaultier de Claubry mentioned, that in a work published by him, the differences between typhus and typhoid fever were examined at length, and that he would present a *resumé* shortly to the Academy. The conclusions were adopted.

Amputation of the Leg just above the Malleoli.—Dr. Lucien Boyer presented a child, whose leg had been amputated by him by this method; the little patient, with the aid of the artificial foot, constructed by Dr. Martin, was able to stamp his foot on the ground, and move about with perfect facility.

On Inoculation of Variola.—Dr. Auzias Turenne presented a monkey, whom he had succeeded in inoculating with the variolous virus. The idea was suggested on reading a lecture of Professor Chomel, in which this distinguished Professor regretted, that when the eruption was doubtful, inoculation could not be had recourse to, as before Jenner's discovery. Two small incisions were made on each upper lid, and variolous matter was inserted. Six days after, two pustules appeared, and on the tenth day, the animal died, after having, a short time previously, offered an eruption of imperfectly formed pustules: at the *post-mortem* examination, the mucous membrane of the respiratory organs was somewhat injected. Since this first experiment, Dr. Auzias Turenne performed the following, on the 14th inst. The matter was introduced into two incisions made on the lids. 17th.—Redness around the wound. 20th.—On the left side there was a small scab, probably because the animal had scratched the part, and on the right a pustule; the animal was not so lively, and was evidently feverish. This experiment was performed in the wards of Dr. Huguier, where the monkey may be examined.

GARLAND DE BEAUMONT, D.M.P., B.L., & S., &c.
Honorary Physician to the Spanish Embassy.

Letters from India announce the death, in his 35th year, of Mr. William Griffiths, who has for years been ardently engaged in the botanical examination of that country, and has transmitted home many valuable communications on the subject, some of which are published in the transactions of the Royal Society. Mr. Griffiths has fallen a victim to his labours, in the fatal climate of Malacca.

PROGRESS OF GERMAN MEDICAL SCIENCE.

By SIGISMUND SUTRO, M. D.

Scarlatina Anomala, Symptomatica, et Critica.—A schoolmaster, ætat. forty-two, was seized on the 21st of Jan., 1842, with a gastrico-rheumatic fever, complicated with pleuritic pains on the left side. Large doses of tartar emetic and nitre produced vomiting and purging, and consequently removed the pleurisy. The fever, however, continued unabated, and even assumed a nervous character on the 29th, which, however, did not increase, in consequence of the administration of infusion of arnica and muriatic acid. On the 2nd of Feb. (the twelfth or fourteenth day of the disease) an erythematous redness appeared, first at the ankles, and spread thence, in a few days, over the calves, legs, trunk, chest, face, and upper extremities; even the palms of the hands and the soles of the feet were not spared. The exanthema appeared in the form of elevated red spots, partly resembling the measles, and partly scarlatina, and was accompanied by some affection of the throat and the Meibomian glands. Inasmuch as the febrile symptoms diminished after the appearance of the exanthema, the latter may be considered as critical. On the 9th of Feb. desquamation commenced, and followed the usual course as in scarlatina, the skin falling off in large shreds, particularly from the hands and feet. The general health of the patient was already so improved on the third day after the desquamation, that he complained of nothing more than restlessness when asleep. Convalescence was very protracted, the patient suffering from weakness of the legs for a long time. He was also affected with rheumatic pains of the extremities in the beginning of March, which extended to the neck and shoulders. A tumour formed on the left side of the throat, scarcely visible externally, but causing much irritation and difficulty of swallowing. It burst on the 17th, during a violent fit of coughing, and the patient expectorated a pint of matter, with great relief. On the 20th the cough had disappeared, and deglutition was easy. But the ultimate recovery was tedious, being protracted by a nervous irritation, which yielded only to the use of the baths of Constadt.—(*Dr. Camerer, of Langenau in Wurtemb. Correspond. bl.*)

Case of Inflammation of the Portal Vein.—A domestic, ætat. sixty-two, strong, tall, and healthy, became ill after the death of his master, which had affected him greatly. After he had suffered for a fortnight with insomnia, anorexia, sensation of pressure in the region of the stomach, &c., the author was called on the 5th of March. The abdomen was not painful to the touch, nor much distended. Bowels gently open from the use of Epsom salts. Tongue rather furred and dry. Pulse ninety-five, rather full and quick. Thirst great. On the 7th he had a rigor, followed by heat, thirst, and frequent pulse, but no perspiration. These attacks recurred daily, but not in any definite type. They were absent only twice in the course of the disease, and during the last three days of his life. His nights were generally sleepless without delirium. The patient took, emuls. inf. ipecac., and sometimes tartar. tartaris. In the night of the 9th of March, he had six thin, greenish-brown, flaky, offensive stools. Rumbling and great tenderness at the cœcal region were complained of. Chest and head free. As long as the diarrhœa was moderate, mucous remedies and aq. chlorin. were administered, but when he had forty thin stools in the third night, and twenty in the fourth, gumm. arab. with tinct. thebaic. was administered and afforded some relief. No tenesmus. Pulse frequent, small, and weak. On the 13th of March, quinine, alum, and camphor were ordered, but the weakness increased, the pulse became more and more frequent, and respiration more rapid, but without *rales*; aphonia. Pain and rumbling in the abdomen. Diarrhœa particularly frequent during the night, stools very thin and offensive. Decoct. lichen. Isl. with extr. cascar. clysters with acetate of lead, and alum whey were of no service. On the 16th, about noon, he became insensible, and died at three,

p. m.—*Post-mortem examination*: Larynx ossified, its mucous membrane pale, without mucus; but little serum in the pleuræ, cellular structure of the lungs dilated; an ounce of clear serum in the pericardium, a small quantity of liquid blood in the ventricles, and a dark red coagulum. The membranes of the vena cava ascendens in the region of the liver normal; in their cavity a large blue-red, loose coagulum was found. Brown ichor partly filled the abdominal cavity; the intestines were injected externally, covered with glutinous, thin exudation. The mesentery of the cœcum was thickened and contained several abscesses; the veins full of greenish-yellow pus; the larger veins were all filled with it, but did not contain any coagula; their membranes thickened, brittle, of a dirty yellow colour. The other part of the mesentery was free from pus; its veins contained dark liquid blood; fluid of a dirty yellowish colour was found in the vena porta. In the parenchyma of the liver towards the surface, brittle blackish spots were discovered, with small collections of pus. The portal branches of the liver contained a dirty yellowish liquid, and the gall-bladder a great quantity of thin yellow bile. The spleen was of normal size, of a brown-red colour, and without much blood. The mucous membrane of the duodenum was covered with black spots, the consequence of injected capillary vessels, and likewise distended. The mucous membrane of the intestinal canal was generally thickened through serous infiltration. The colon was also thickened, and its mucous membrane covered with a thin purulent exudation. Vena cava inferior filled with liquid blood, the membranes normal. The author mentions the distinct paroxysms of rigors as a characteristic sign of pyæmia; but pyæmia, produced by inflammation of vena portarum, is distinguished by the want of some usual phenomena accompanying the pyæmia produced by other diseases, such as endocarditis or inflammation of the lymphatic vessels. Other phenomena are peculiar to this particular pyæmia, such as the sensation of pressure in the abdomen, &c. The author also considers the non-affection of the sensorium as characteristic, and endeavours to explain it by the impediment to the circulation of the diseased blood met with in the hepatic capillary vessels, so that it cannot alter so easily the blood in the large organs, as in those cases in which pus proceeds from the lympathic vessels into the veins, and from the veins into the heart. The author likewise explains the changes observed in the other abdominal organs, such as capillary injection, and infiltration of the intestines, peritonitis, exudations, &c., from the same impediment of the circulation of the purulent blood in the liver.—(*Dr. Frey, of Mannheim, in Heidelb. Annalen.*)

TRANSACTIONS OF LEARNED SOCIETIES.

Royal Medical and Chirurgical Society, May 27th, 1845. Dr. George Burrows in the chair.

Case of Intus-susception, in which the Intus-suscepted portion of Bowel sloughed away, and was voided by the Rectum—Recovery of the Patient. By S. J. Jeaffreson, M.D. and L. M. Cantab., Physician to the Chelsea, Belgrave, and Brompton Dispensary.

The case was that of a young man, ætat. 17, to whom the author was called on the 26th May, 1844. He was labouring under general febrile symptoms: there was an anxious expression of countenance; the abdomen not tender under pressure, but becoming tympanitic; nothing could be retained on the stomach; the matters vomited had a grass-green appearance; there was painful tenesmus without evacuations. Calomel and opium, purgatives of senna, croton-oil, &c., with turpentine enemata were used up to the 28th without success. On that day, the author considered that decided symptoms of inflammation of the bowel and peritoneum had set in; the belly was generally tender, especially in the left hypochondrium, where a distinct hard tumefaction was observed. Leeches, fomentations, &c., were used in addition to the other means, but no evacuations took place until the 31st, when there were very copious and offensive discharges from the bowels, and the vomiting ceased. From this date the patient gradually recovered; copious evacuations took place, charged with much gelatinous-looking mucus, and on one occasion a small quantity of blood.

On the 8th of June there was discharged from the bowels, what the author supposed to be either a portion of the small intestines, or a cast of it (of coagulable lymph); it was about two and a half to three inches in length, and of a tubular form; most horribly putrid, and one or two minute points presented the appearance of sphacelus. After this, with some slight interruption, the patient recovered.

The substance voided was examined under the microscope by Mr. Toynbee, who stated that he found cellular tissue, traces of blood-vessels and nerves, and epithelium. Mr. Dalrymple, who also examined it, thought that involuntary muscular fibre might also be detected, but could not speak positively, from the preparation having been placed in spirit of wine for some time.

The author draws attention to one point in the treatment, viz.—the abstinence from any active depletion on the 28th, when symptoms of inflammation had decidedly set in. At this period he observes, a free evacuation of blood would, probably, have reduced the inflammatory action, and relieved the immediate sufferings of the patient, but it might also have masked the symptoms, and checked the reparative processes of adhesive inflammation, on which the recovery of the patient depended.

Dr. Webster agreed with the author of the paper that such cases were exceedingly rare, especially in those instances where recovery takes place after strangulation and separation of part of the bowel. He had been called in consultation with Dr. Webster some years ago to a case of the kind, which occurred at Dulwich. The symptoms at first were very obscure, but afterwards evidences of obstruction set in, followed by the separation and discharge of a part of the bowel, twenty-seven inches in extent. The patient recovered. The preparation is in the Museum of the University College.

Dr. C. J. B. Williams was rather surprised that the author of the paper and Dr. Webster had stated that these cases were exceedingly rare; it might be so with regard to each man's individual experience, but not so collectively. Many such cases had been recorded, not merely where inches, but feet of the intestines were expelled. He (Dr. C. J. B. Williams) had that day read an account in the Transactions of the Medical Society of Bombay, of several cases of dysentery, in which such an expulsion of a portion of the bowels occurred. And, indeed, it seemed in that disease to be the common mode of cure adopted by nature, when the disease had proceeded to a certain extent. Such cases may, indeed, be rare in relation to the ordinary proportion of disease, but they were not rare in reality.

Dr. Burrows was desirous to learn the experience of army surgeons, who had practised in tropical climates, with respect to this mode of termination of dysentery.

Mr. Fitzmaurice, as an old army surgeon in Ceylon, begged to express his opinion that it was by no means an uncommon circumstance: it almost invariably happened in severe cases of dysentery, occurring among the native soldiers, but not among the Europeans. The disease under those circumstances, was known by the name of sloughing dysentery; sometimes from eight to nine, twelve, and even eighteen inches of intestine were expelled. There were several preparations of this kind in the Museum of the Ordnance Department at Woolwich. They had been sent over by himself and other army surgeons.

Dr. Webster believed that such a result might occur much more frequently in the warm climates than in the colder ones.

Dr. Gregory remarked that not many weeks since they had discussed in that Society the subject of tubular formations in the intestinal canal, and, at a hurried glance at the preparation which had been sent round, he thought it resembled those productions. He would be glad to know in what existed the difference between them?

Dr. G. Burrows said, that he presumed the author of the paper based his opinion as to the nature of the expelled membrane, upon the statement of Mr. Toynbee, who had examined it under the microscope, and had detected in it epithelium, vessels, and involuntary muscular fibres, &c.

On a Systolic Murmur in the Pulmonary Artery, and its Application to Diagnosis, by Edward Latham Ormerod, Esq., scholar of Caius College, Cambridge. Communicated by George Burrows, M.D.

The general object of this paper was to shew the existence of a murmur in the pulmonary artery in certain cases, and to draw some inferences as to the nature of such cases. A murmur was presumed to have its seat in this artery, when it could be traced from the left edge of the sternum in a line from the third intercostal space, or a little higher, towards the middle of the left clavicle for about two or two inches and a half. To prevent any collusion from alteration of the size or situation of the heart, or confusion of sounds, cases of recent disease only were employed, and of these only such as allowed the murmur in the pulmonary artery to be accurately defined at one time or another.

There were two classes of these: those, namely, in which some or all of the murmurs had disappeared during the progress of the case, and those where no change had occurred, so long as the patients continued under observation. The different observations made of these cases were registered in a tabular form, which the nature of things did not allow being read to the society. The numerical analysis of the cases, as far as the murmurs were concerned, will not allow of abridgement, but it was shewn that the murmur in the pulmonary artery was one of the earliest to develop itself, and the last to disappear.

The cases were next considered as to the nature of the disease during which the murmurs appeared. They seemed generally divisible into two classes, namely into anemia with its kindred maladies, and acute rheumatism. The former class was passed lightly over, to allow more time for the consideration of the latter, on which indeed the practical interest of the paper rests.

It appears that a murmur of the pulmonary artery may, in an enormous majority of cases, be considered independent of organic disease, and further, that it is *possible* that the cause producing a murmur in the pulmonary artery may be identical with that producing a murmur in the aorta. It is generally admitted, as far as concerns adults, that murmurs are producible in the direct ratio of the attenuation of the blood, and such attenuation is known to attend acute rheumatism, depletion, and the use of mercury, as well as chlorosis. So there is at least a possible cause of a murmur in operation in these cases. All this, however, is to be viewed with great suspicion, when we remember the frequency with which the valves of the heart really are affected in acute rheumatism, and consider that there may be an anemic murmur in the pulmonary artery at the same time as an organic one in the aorta.

A general probability is rarely if ever applicable to an individual acute case, so that the recognition of this murmur cannot help us much under such circumstances; but when the acute stage is past, we may find in it a means of discrimination between the general and local effects of diseases—the curable and the incurable. The diagnoses between functional and organic murmurs of the heart, so far as auscultatory signs are concerned, rest chiefly on the variable or fixed situation of those murmurs. The value of this sign turns on its allowing us a more extended field of observation; and for a lengthened period. The acknowledged difficulty of the subject renders us willing to accept the assistance of a sign which is offered, not in disparagement of what we already employ, but in aid of them.

Dr. C. J. B. Williams remarked that it was not possible rightly to estimate such a paper as that which had just been read in abstract, as the cases and the tabular information would require careful consideration. If, however, he had not mistaken the meaning of the author, he implied that there was a certain mode of diagnosis between the murmurs resulting from a diseased state of the valves

of the pulmonary artery and the aorta. As he (Dr. C. J. B. Williams) was the originator of that plan of diagnosis, he would wish to state the results of additional experience both as showing how far that opinion was correct, and to what extent also he had been led to modify it. If the murmur with the first sound of the heart be heard at the middle of the sternum and along its upper part, and also in the carotids, it might be fairly regarded as arising from obstruction of the aortic valves, and that too whether it was heard the louder at the left or right margin of the sternum, as it may be heard in either situation, the variations depending on the position of the heart, the density of the intervening parts, &c. It is not, however, a necessary consequence that a murmur unattended by all these characters, should be pulmonic. When the murmur arising from diseased aortic valves is slight, it may be recognised at the middle of the sternum, and yet not be powerful enough to be audible in the carotids, unless something should occur to excite the heart's action, in which case it will be perceptible in the vessels of the neck, and its connexion with a diseased aorta rendered no longer doubtful. This state generally occurred in anemia, in consequence of the vessels being only partially filled, and therefore rendered bad conductors of sound; and such he (Dr. C. J. B. Williams,) was apt to believe was the case in the majority of Mr. Ormerod's cases, in which the pulmonary murmur was supposed to have occurred. He (Dr. C. J. B. Williams,) did not agree with Dr. Hope, on either anatomical or pathological grounds, that the pulmonary murmur could be heard in the situation of the valves, and to the extent of two inches and a half upwards to the left side; nevertheless, he still thought it possible to diagnosticate cases of pulmonary murmur. If the sound were audible in the middle of the sternum, and not below the left breast, nor at the summit of the sternum, nor in the vessels of the neck, at which, however, the natural double cardiac sound was nevertheless audible, then there would be reason to judge such murmurs to be pulmonary. He had met with a few cases in which this peculiar murmur could be recognised, but these were decidedly rare, thus corresponding to the rarity of lesions of the pulmonary valves discovered after death. He had also heard it in connexion with disease of the lungs, and sometimes accompanied by bellows-sound diffused at the root of the lung. In general, murmurs heard at the middle of the sternum originated in the aortic valves, and unless Mr. Ormerod could shew by additional evidence that his cases were not connected with a diseased state of that vessel alone, he, (Dr. C. J. B. Williams) could not regard them as substantiating his (Mr. Ormerod's) argument.

Dr. Copland was gratified at hearing the remarks which had just fallen from Dr. Williams, because he (Dr. Copland) had some time ago, in the article on "the Heart," published in his Cyclopedia, differed in opinion with Dr. Hope on the diagnosis of these murmurs, and he then gave a summary of the views which had just been stated by Dr. Williams, in every one of which he fully agreed.

Dr. George Burrows was desirous to draw Dr. Williams' attention to the fact, that the observations of the author related to the occurrence of pulmonary murmurs, produced by functional disorder, such as those produced by anemia, &c., and not by structural disease. Although the latter are certainly rare, functional disorder is far from being uncommon, and might give rise to the murmurs described by Mr. Ormerod.

Dr. Copland observed that the difficulty in these cases of referring the murmurs to their seat, arose from displacement of the heart, from various causes.

Dr. Theophilus Thompson was of opinion, that a source of error might be found in murmurs arising from the aorta, which from certain peculiarities they presented, might be supposed to originate in the pulmonary artery, and in illustration of his remark, he referred to the case of a young woman, who had been recently a patient of his, and in whom he could distinguish a murmur between the base of the heart and the left clavicle. It was not audible in the carotids, nor on the right side of the sternum, but was chiefly perceptible about an inch or more to the top of the sternum, and in the second intercostal space. He thought this sound was produced by some cause connected with the arch of the aorta, but there were several symptoms in the case which rendered even that opinion doubtful, and it was ultimately removed or at least masked by the puffing respiration caused by a large cavity in the lung. When the body was examined after death, the heart was found to be higher up than usual, but its inner surface and the valves were healthy. There was some deposit on the surface of the aorta. There was also a large cavity in the left lung, and a considerable effusion of lymph on the pleura, more marked at that part of the membrane which was in contact with the pericardium. Dr. Thompson thought that in this case, from the situation of the murmur according to the account given by the author of the paper, it might be regarded as produced by the pulmonary artery, and might therefore be taken as a proof that it is not always possible to ascertain precisely the situation of such a murmur.

Mr. Ormerod stated that the murmurs alluded to certainly were not in the aorta, and it remained for those who said they were not in the pulmonary artery to show where they were. That the situation of the pulmonary artery allowed its murmurs to be heard at least as clearly as did that of the aorta. And that such murmurs really could be heard there, was proved in the only two cases of disease of the pulmonary valves with which he was acquainted, by a direct diagnosis having been made by attention to the rules laid down by Dr. Hope. The preparations were in the museums of St. Bartholomew's Hospital, and Cambridge University respectively.

Dr. Williams in reply stated that the ordinary causes of murmurs arising from functional derangement are an attenuated state of the blood, and an inflammatory irritation of the cardiac orifices, both of which would have more influence on the aortic than on the pulmonary valves. The attenuated state of the blood would certainly be shown by murmurs at both orifices, but it would be more evident at the aortic, as the rush of blood was greater there than at the other; and the other cause, inflammatory irritation, would from the same reason, be more marked at the aperture of the aorta, and also because that part is more liable to take on inflammatory action than is the pulmonary artery.

Mr. Ormerod said, that as Dr. Williams justly remarked, the paper could not be judged of without examination of the facts recorded in the tables, but that there he felt sure proof would be found that all sources of fallacy had been obviated by a careful selection of cases. That it had been clearly ascertained in all these cases that a murmur could be heard definitely in the situation described, and that the position of the apex and sigmoid valves had also been carefully ascertained.

Dr. Kingston observed that the use of the stethoscope alone is not to be depended on in attempting to ascertain the situation of murmurs in the chest connected with the heart; the previous history of the case should also be taken into consideration, and by its means the difficulty of diagnosis between affections of the right and left sides of that organ would cease. If the sound which is heard has followed inflammation of a rheumatic origin, or other primary disease of the heart, it might in general be regarded as caused by a diseased condition of the valves of the left side, but if on the other hand it succeed chronic disease of the lungs, it is in all probability produced by dilatation of the right side, the result of obstruction to the circulation caused by the diseased state of the lungs. The character of the pulse, with other general and local symptoms, especially those connected with the carotid arteries and jugular veins, will aid very materially in forming an opinion as to the nature of the existing disease. The stethoscope should not be regarded in such cases as the sole means at the command of the practitioner to enable him to form his diagnosis of the case.

Dr. Burrows said that it should be borne in mind that the author had not attempted to lay down any rules for the diagnosis of diseases affecting the right side of the heart. He expressed his surprise that Dr. Williams was so diffident in pronouncing an opinion respecting these murmurs at the orifice of the pulmonary artery. In advanced disease of the heart it certainly was difficult of detection, but not in recent cases, such as those detailed in the paper. He (Dr. Burrows) could see no reason to doubt the existence of the pulmonary murmur in these cases. It had fallen to his lot to observe in certain stages of rheumatic fever, a murmur at the commencement of the pulmonary artery, which had not been previously described. He thought Mr. Ormerod's paper one of great practical importance, more especially if there could be found in his cases any one sign, by the occurrence of which we might be enabled to give a more favourable prognosis than usual.

Dr. Taylor observed that as the time of the society had just expired, he would detain them only while he made some brief observations on one or two points. With respect to one of the indications of the seat of the murmur, alluded to in several cases noticed in the communication which had just been read, he thought it had not been sufficiently considered by Dr. Williams. The murmur was said to have been heard on the left of the sternum, over the base of the heart, to the extent of from two inches and a half to three, in a line drawn from that part to above the middle of the clavicle. If then this murmur was caused by disease of the aortic valves, as it was heard so far in the course of the arch, it should be also audible in the carotids; if however it were connected with the pulmonary valves, then, bearing in mind the course of that artery, and its situation deep in the chest behind the aorta, it becomes probable that a murmur so loud as it must necessarily be, if it originated in the aorta, must be perceptible also in the vessels of the neck at the same time. He (Dr. Taylor) was fully persuaded, however, and in this he agreed with Dr. Williams, that the fact of a murmur heard in the middle of the sternum, and unaccompanied by the same sound in the carotids, did not of necessity show that disease of the aortic valves was not the cause thereof. He (Dr. Taylor) did not wish to express an opinion as to the correctness of the diagnosis in Mr. Ormerod's cases; there was some apparent doubt attending them, and it would be requisite before coming to an opinion, to institute a careful examination of the cases which were reported, but he thought it right to add that during many years in which he had paid considerable attention to diseases of the heart, he had never seen an instance in which the existence of a murmur could be traced to disease seated either in the tricuspid or pulmonary valves. He had found a diseased state of these valves after death in several cases, which perhaps, might during life have caused such a murmur as that described by the author of the paper, but as the heart had not been examined during the life-time of the patient, the existence of such a murmur had not been ascertained.

REVIEWS.

A Physiological Essay on the Thymus Gland.—By John Simon, F.R.S., &c. &c. Renshaw, 1845.

We need hardly remind our readers that a sum of £300. was willed by Sir Astley Cooper to be awarded, every three years, to the author of the best essay elucidating some of the dark points in physiological anatomy. The subject first fixed on was the Thymus Gland; one affording an ample field for research,—nothing definite being hitherto agreed on by physiologists. The author of the essay before us is the fortunate winner of the maiden prize, and in our judgment he richly deserved it.

Passing over the first chapter, which contains much historical research, we proceed to lay before our readers a summary of the facts elucidated, and the views our author has founded on them. The more minute details of the external anatomy of the Thymus glands are wisely omitted, being previously well known; and Mr. Simon at once proceeds to the mode of develop-

ment of its structure. The thymus gland may be seen by the naked eye, or at all events, in fœtuses by a simple lens, one and a half inch long; and by careful manipulation under the microscope, it may be traced in fœtuses of half-an-inch in length.

The earliest form in which I have discovered it has been that of a simple tube; lying in the animals I have mentioned, (swine and oxen) along the carotid vessels, and surrounded by the faint indications of nascent areolous tissue. The contents of the tube are seen, (with a magnifying powder of 400 diameters) to be granular and dotted, but do not as yet shew distinct corpuscles. Its figure is defined by the abrupt outline of the membrane, which constitutes its wall; an exquisitely delicate, transparent homogeneous tunic, presenting at regular intervals, slightly elongated thickenings in its substance.

Mr. Simon's researches refute the views of Arnold and Bischoff, that it is a process of the respiratory mucous membrane, or, that it has any connection with the thyroid body.

The second stage in the progress of its development is in analogy with the mode of growth attributed to the true glands; the tube bulges at certain points of its length on one side or the other; and gives origin to diverticula or follicles, which maintain their connexion with its cavity. * * * In the portions of the gland where they are most thronged together, these may be seen in profile forming a series of flask-like appendages to the tube.

The follicles next begin to ramify, two or four sprouting from the fundus of the old one. These again sprout, forming bunches, connected to the primary tube by the stem of the first follicle; so that the permanent structure of the gland may be named "*tubulo-vesicular.*"

Sir Astley Cooper by injecting the substance of the gland, and Mr. Simon by following its development, both arrive at the same opinion, viz., the persistence of a central cavity; i. e., "the above-described primary tube, which, though increased in size, is yet hidden from casual observation by the abundant peripheral off-shoots developed from it; and which, when exhibited by the former modes of preparation, had been seen with a deceptive exaggeration."

With regard to the important question of the period of its greatest development, Mr. Simon gives a table containing numerous experiments by Haugsted with twenty-four original observations, in all sixty-four; from these he deduces the fact, of its greatest development occurring after birth during "the age of early growth."

The general and rough results of the examinations in the human subject, seem to be the following · 1st. During the period next succeeding birth, the activity of the thymus is remarkable; it increases considerably in size, becomes tinged with secretion, and its specific gravity is lowered by the greater fluidity of its contents. This first growth is far out of ratio to the general increase of the body. 2dly. For several months, it continues to increase at a diminished rate, and merely in proportion to the general growth of the body; its further enlargement ceases about two years after birth. 3rdly. From this time, during a *very variable* number of years, it remains stationary, and, supposing the individual to be adequately nourished, gradually assumes the structure of fat. 4thly. The duration of its decay, and the epoch of its entire vanishing are still more uncertain; about puberty, it seems in most cases, to suffer its chief loss of substance, and to be reduced to a vestigiary form.

The full account given of the development, prevents the necessity of dilating on the mature structure; "for the arrangement of the cavity of the gland is but a complication of the tubulo-vesicular form of its early growth, and the wall that cavity is but the same homogeneous membrane, which bounded it from the first period of its distinct existence."

The cavity contains a fluid, floating an immense number of microscopical corpuscles. Chemical analysis shows the fallacy of the theories of Tiedemann, Arnold, and others, that the thymus is a receptacle for carbon before respiration has commenced, as it contains no more carbon than blood, muscle, &c. It is impossible to obtain a sufficient quantity of its secretion for chemical investigation, without some portions of the gland itself, but its ultimate composition may be almost expressed by the formula for practice. We may therefore, "venture to describe the secretion of the thymus gland in the young animal as nutrient matter."

To the study of the comparative anatomy of the thymus, Mr. Simon has devoted great pains, and the general result of his dissections is the discovery,—"That the thymus gland belongs, without exception, to all animals breathing by lungs, and to no others;" and in hybernating rodentia it becomes a persistent organ, and is filled with fat.

We have now a chapter in which our author passes in review the structure of the true glands in general, and their stages of cell development in order to compare them with the same processes, in the glands without ducts, as a natural family.

In the thyroid body, the habitual stage of all development is that of the dotted corpuscles, which are seen floating in the pellucid fluid that fills the natural cavities of the gland.

These are analogous to the cytoblasts of the true cells, and in some instances the cell membrane may be developed.

In the supra renal glands there is likewise a considerable range sometimes for differences of structural development. Generally, however, the cytoblast remains undeveloped. There may accordingly be traced in these bodies all the steps of cell growth. 1st. The free cytoblast, next the definite arrangement of molecules round it, as their centre; and thirdly, the inclusion of all within a membrane which completes the cell.

In the spleen cells never occur with any approach to perfectness; the well known Malpighian vesicles consist entirely of mere dotted corpuscles, lying bare within a capsule of arterial capillaries.

In the thymus, one would at first believe a similar low stage of cell development to be universal; for, in examining the contents of the gland in early life, one finds no trace whatever of complete cells. It is however shown, that under certain circumstances, the ultimate structure of the gland undergoes a change, in the course of which its dotted corpuscles evince their true nature in the clearest manner, by entering, as genuine cytoblasts, into the structure of nucleated cells.

The *limitary membrane* admits of demonstration in the glands without ducts, co-extensively with its existence in the true glands. In the thyroid body, where it is very strong and distinct, it assumes the arrangement of closed vesicles.

In the supra-renal glands, the limitary membrane has an inferior, though often distinct development.

In the Malpighian bodies of the spleen, the limitary membrane is absent.

In the thymus gland, the reader will identify it with that single diaphanous membrane, which, in early embryonic life, formed the primary tube of the nascent gland; he will remember how, by bulging and branching, it formed a ramified follicular system; and how it has been seen to constitute in the mature organ, the exact boundary of the parenchyma.

The ultimate distribution of vessels is the same in the glands without ducts, as in the true glands; it consists in "the distribution of a perfect capillary net-work around the assimilative elements."

The chief difference existing then between the true glands and those without ducts, is, that the true glands secrete cells as a general rule, whereas in the glands without ducts this is only exceptional, the cytoblast not being generally developed into the cell: and from the peculiar arrangement of the limitary membrane, the secretion is confined within the cavity of the gland.

Our author presents, therefore, the following general facts:—

First, that in most animals, the gland only occurs temporarily. The secreted matter then presents itself in a fluid form, and is related to the universal material of nourishment, the liquor sanguinis, by the closest affinity of ultimate chemical composition. Secondly, that in some animals, after discharging this temporary function, the gland gradually passes into the permanent exercise of a different, but analogous act of assimilation, and manifests its secretion *in the solid form of fat.*

The first occurs in young animals, the second in hybernating animals, previously to their winter torpor. "On a comparison of these instances, it is easy to say, what the conditions of hybernation and early life, have in common; in both, the waste of animal tissue is reduced to a minimum. The gland is never present without lungs, the period of its persistence bears inverse proportion to the muscular activity of the individual." Mr. Simon concludes therefore, "that the thymus gland fulfils its use as a sinking fund of nourishment in the service of respiration."

In conclusion, we must say, that from the close reasoning and general style of this monograph, as well as from the laborious research displayed, we have received a treat, such as does not commonly fall to our lot.

NOTICES TO CORRESPONDENTS.

A Subscriber, Bedford.—*The opinion of Dr. Davis has reference to the strict legal right to practice. But registration as Physician will depend, according to a letter from Sir James Graham, on the possession of a proper diploma as M.D. from any British or Irish Corporation, whose Charter empowers it to grant such a degree.*

Medicus, *referring to the "able and judicious letter" of Medico-Chirurgus in our last number, shares strongly in his condemnation of the plan of restricting to Physicians the title of Doctor, and maintains that in practice, clause 38 (making the assumption of the title, Doctor, by any but Physicians, a misdemeanour) could not be enforced—for the public feeling would be against it, and thousands may be Doctors without being Physicians. The possession of the highest diploma should not preclude—our correspondent maintains—the possessor from adopting that kind of practice which best suits the circumstances he is placed in.*

D. C. O. *has mistaken our meaning. We feel no hostility to the Glasgow "Faculty," but simply gave our opinion as to the state of the present law, and the probable effect of the New Bill on that body. The pamphlet was already in our possession, and as we do not know the name of our correspondent, we cannot return him the duplicate.*

W. P. D.—*The "Dublin Licentiate" will not register as a "Fellow of the Royal College of General Practitioners," unless resident in England. The steps to be pursued as to time and mode of registration, will be fixed by the New Bill.*

Acarus *sends us a sweeping denunciation of what he calls the "spiteful factiousness" and "miserable jealousy" of a "thick and thin" Medical Journalist, in Dublin. Our correspondent has not been well treated, but he stands precisely in the same case with all those who have been brought into similar unfortunate association. The extent of the circulation of the* Medical Times *in Ireland has entailed on us the tax of suffering the "jealousy" Acarus speaks of; but from studied silence—that speaks volumes—to unstudied vituperation that would utter daggers—we pass all by unheeded. It*

is the tooth of envy on the unhurt file. In the hope that Acarus will see, with us, the wisdom of patient forbearance, we shall postpone,—if we do not decline—his letter.

Mr. Greensell (Lewisham).—*The curriculum of the Royal College of General Medical Practitioners will be fixed by the New Council of forty-eight. What it will be we cannot yet of course say. We cannot, however, doubt that "Lectures" will be required.*

F. R. C. S.—*The sixteenth clause appears to us to give all General Practitioners who are forty years of age, the right,* ipso facto, *of being examined by a Royal College of Physicians, without any question as to the curriculum of study they may have gone through. M.D. and Physician are made equivalent in the Bill.*

Quiz *calls our attention to a resolution passed but in March last—three short months since—which Mr. Bottomely seconded. It run thus:*—"That this Meeting appreciating the laudable exertions of the Society of Apothecaries during the last thirty years, in the cause of medical science and education, and sensible of the advantages that have consequently been insured in the professional acquirements of the General Practitioner of Medicine—cordially acknowledges the benefits the Society has conferred both on the profession and the public. The Meeting desires further to express its thanks to that body for the disinterested conduct they have evinced in disclaiming any corporate or particular interest, while advocating the claims of the General Practitioner to *a separate and Independant Incorporation.* The Meeting trusts that the Society, at the present important crisis, will be ready to intimate to the Government its desire to be relieved as a Corporation, from any further control over medical affairs, and that it will use its best endeavours to forward the wishes of the great body of General Practitioners in securing their proper position in the present Medical arrangements of the Government." *Quiz asks, if the last College Manifesto, since published, was so satisfactory to Mr. Bottomely that it made him turn tail?*

Mr. Masters, Liverpool.—*The diploma of the "Faculty" at Glasgow will undoubtedly entitle the holder to register in England as a General Practitioner, and to charge for advice and medicine.*

M. R. C. S. and L. A. S.—*We have read this clever letter with much attention. We see nothing in the Bill to prevent gentlemen, now in practice, registering in a two-fold manner. First, as "Fellows of the Royal College of Practitioners," under clause fourteen; and secondly, under all their present titles, whether as Physicians, Surgeons, or Apothecaries in the Supplementary Register, under clause thirty-three. No arrangement can be more just—none more sensible—none more universally satisfactory—and Sir James Graham will have the less objection to it, as fees follow each registration. This is clearly the meaning of the Act, and the intention of Government. To complete the arrangement, however, a short clause would be useful to say, that the General Practitioners now in practice, might recover as such, though registered also as Physicians and Surgeons.*

The letter on "Medical Assistants" will be considered.

We are obliged to our Manchester Correspondent in reference to the hint about "Students," &c., and should more leisure offer, hope to communicate on the subject by letter.

Several correspondents address requests to the publisher in notes to the editor. The error causes much extra trouble in a quarter sufficiently visited by that unwelcome guest, and often frustrates the wishes of the writers. All requests about forwarding numbers, &c., should be addressed in special notes to the publisher.

Z. Z.—*Under the name of Associates, all Physicians, members of Colleges of Physicians—whether Fellows or Licentiates—appear to us to be included. The Fellowship of a Scotch College would give, apparently, the same degree as in an English College, on the removal of the possessor to this part of the country.*

Mr. Purdie's *advertisement about* £100,000, *required a shilling, he says, to be sent him, not a penny. Do our readers remember Canning's needy knife-grinder? We have not sent our shilling.*

The article on "Irish Asylums" shall receive attention.

H. A.—*An M.R.C.S. may register as General Practitioner.*

A General Medical Practitioner and Member of the College for Twenty Years *has heard the proverb, about looking "gift horses in the face." We must not be over-exacting. There is a point in the bead-roll of prayers and concessions when the most obliging gentlemen will turn restive. Our correspondent is in error in a few points. In our opinion, the "Preliminary Examination," which will not be* medical, *should be conducted by Members equally from the three Colleges, or by gentlemen totally unconnected with the Profession:* ex. gr., *some of the Examiners of the University of London. That no man without a good preliminary examination should be admitted to a learned profession, is a piece of obvious common sense.*

Dr. Nugent's *letter has been received. It shall be left at our office for the advertiser. We trust that our correspondent is not* very *sanguine about the* £100,000.?

A Second-Year's Student, Manchester, *who gives us his name, replies to a scurrilous attack on his professors, published in a "scandal-mongering" contemporary. The charges advanced are, we are assured, false and unfounded, and have no better support than the assertions of one or two first-year's students, irregular attendants of the hospital, and made splenetic by their failing to secure a third anatomical prize. The temporary stoppage in Mr. Davis's lectures arose from medico-legal investigations, which* forced *his attendance at Liverpool, and he offered to make up the missing lectures, but failed to muster a class for the purpose. The accusations against Mr. Turner and other gentlemen who have grown "grey in professional services," are said to be equally well-founded, and any incivility of the nurses only showed that the conduct of the recalcitrant "juniors" did not recommend them to that respect* gentlemen *can always secure from servants. With this analysis of a very elaborate letter, made in our anxiety to shield professional teachers from light or wanton accusations, we must end this unpleasant subject.*

A Subscriber.—*A Scotch graduate, by registering in the Supplementary Register, will retain all his present titles and honours. A youth under* 21, *practising before* 1815, *cannot, on that title, register as a General Practitioner.*

Mr. Butler Lane *has not correctly apprehended the meaning of clause* 15. *It does not refer, in* fact, *to existing* members, *who may register forthwith as "surgeons." The truth is, that Sir James Graham, to complete the harmony of his Bill, and carry out his own intentions, must make the Fellows of the Surgical College* Doctors *of Surgery. We are aware of the strong feeling of Sir Benjamin Brodie, and the Council generally, to the title of "S. D.," but they will find it impossible*—actually *impossible—to limit the term surgeons, either in this generation or the next, to Surgical Fellows. The gentleman who sets a fractured limb or amputates a thigh is a surgeon, and will be called so as long as words carry a meaning. In the former Bill there was a clear design shown to restrict the title "surgeon" to the Fellows. We denounced the project at once as palpably impracticable, as well as seriously unjust: and so strong was the feeling against any such design that an official assurance became necessary to the effect that existing members might retain their title of surgeons. This liberty continued, and expressly provided for in the present Bill, destroys every possible chance of restricting at any time, no matter how distant, the term "Surgeon" to the Fellows. If the "Fellows" must be registered as a class distinct from the Members, they have no choice but to register as "Doctors of Surgery." They cannot, and ought not, monopolize a term which, in its ordinary meaning, is applicable to every properly educated medical man. We are quite conscious that from the jarring claims and interests of so many classes of Practitioners, every arrangement must have its difficulty; but we much mistake if the old-fashioned arrangement we have suggested, would not simplify many troublesome complications, and leave the fewest persons dissatisfied.*

A Well-wisher.—*An M.R.C.S. with a diploma before the Bill become law, is allowed by the present scheme to call himself "Surgeon." The "Apothecary" may either so designate himself, or as "General Practitioner."*

Chirurgus *sends us some strictures on the* Medical Gazette, *which declined to publish a letter of Medico-Chirurgius, controverting that journal's policy. The censures seem to us—we regret to say—not entirely ill-founded, but pre-engagements preclude our admission of the letter.*

Mr. Davis.—*Gentlemen now entering as Students will depend on the decision of the Council of Health, as to the recognition of any claim to be exempt from the New Act.*

Numerous letters have been received, not here noticed. The writers will either find them answered in our other replies, or obtain consideration for them in our next.

Several communications have been received, which will be carefully considered. Some papers are unavoidably omitted, which will appear next week.

T. W. W.—*Yes.*

M.D.—*The new Physician will register as a Physician, and get the benefit of that registration; and no more.*

In answer to numerous correspondents, we have to announce that the action brought by Mr. Wakley against this Journal, is yet to be tried by "Writ of Inquiry." A question is now pending decision, whether that writ of enquiry shall be executed before the Court of Exchequer or not.

M. D. (Edinburgh).—We have no time to indulge in the luxury of sending private notes on public business. The questions put are answered in a former notice. Gentlemen must overrate considerably our love of writing when they fancy that in addition to the heavy mass of writing imperative duty imposes on us, we can gratify our cordial love to our tens of thousands of subscribers by addressing them private notes. It would be a great pleasure—but unfortunately is beyond our reach. We have not the arms of Briareus and when two eyes close, we have no others to see by.

A West Essex Surgeon can register as a General Practitioner if the Bill pass, or as a Surgeon—without any further examination.

Mr. C. S. (Greenwich).—The Jena degree will prove worthless, being simply the product of a purchase. It never was worth anything and never will be. C. S. may register as a Surgeon—or if he wish to register as a Physician—must procure a diploma as M.D. by examination before the bill pass.

THE MEDICAL TIMES.

SATURDAY, JUNE 7TH, 1845.

"Omnes qui magnarum rerum consilia suscipiunt æstimare debent, an quod inchoatur reipublicæ utile, ipsis gloriosum, aut promptum effectu, aut certe non arduum sit. Simul ipse qui suadet considerandus est adjiciatne consilio periculum suum; et, si fortuna cœptis affuerit, qui summum decus acquiratur."—TACITUS.

MONDAY is fixed on for the next Parliamentary movement on Medical Reform. We look forward to that evening's performances with an interest heightening as the drama approaches its *denouement.* The plot is palpably thickening; agencies coming into play more complicated and enchaining; incidents hourly multiplying; intrigue, hate, opposition, support, are assuming new aspects, and between us and the final wind up of the tumultuous comedy or tragedy, all is darkness! There stands between us and the *denouement*, a veil so impenetrable that even the lights and shades in the career of a Wakley, or the more fortunate Joseph Ady, might be safe under it.

Shall we have a bill or not? A new College or not? A settlement of medical grievances or not? These are the dark questions to be decided within the next four days, by fierce warfare between no uninteresting or weakly combatants. On one side is marshalled a diversified host—all who hate the Bill for any cause. *There* will be found the dignified Corporators, who, feeling things right for them, believe their creed, that things are right for all others,—optimists in faith, through the most irrefragible of convictions—interest, who resist the heresy of improvement with the fervour of martyrs. There, also, are the dreamy creators of Utopian perfections—worthy men!—who would reject heaven itself, if

their fancy could pourtray to them something better. And with them may be found your men of crotchets, who cut blocks with razors, and see a zigzag in the straight line of a mathematician. And your persons of weak intellect, who fear phantasies of their own conjuring, and take up the current delusion of the hour. And finally, there may be discerned your busy, vulgar fellows of low virtue, who have a traffic to make, or wounded vanity to avenge. Not small that moving flood of men, and not beneath a study the active head whom the fermentation of circumstances has worked up like unburdened froth on the topmost surface. Never was a man more fitted to command a low troop of political freebooters permanently, or to make even a larger and more diversified band effective for a sudden service. Not wanting energy—courageous to a fault, where there is no *personal* danger—unhampered by one needless punctilio as a gentleman—unfettered by one unnecessary scruple as a moralist—full of small expedients and *ruses* as a smuggler-leader or guerilla-general — capable from his intimate, sympathetic, knowledge of low human nature, of miraculously managing the most discordant group of *mauvais sujets* the Profession could muster for him; in short, a reduced and rather clumsy edition of Belial—except, of course, in all that is "infernal" in the description

——---- False and hollow, though his tongue
Dropped manna, and could make the worse appear
The better reason to perplex and dash
Maturest counsels, for his thoughts were low,
To vice industrious, but to nobler deeds
Timorous and slothful; yet he pleased the ear.

Such is the array—such the leader to be marshalled against the new Bill.

Who oppose them? The main mass of the Profession. The Physicians and Surgeons of Ireland and Scotland, almost without an exception, with a great proportion of those of England, including about two-thirds of the body of General Practitioners. The force for the Bill shews numbers and respectability, but no enthusiasm—not much energy—no great cohesion. They side for the Bill, but partially, and then on grounds different, and sometimes conflicting:—are not, in every case, proof to a sophism—rely on no man's honesty very implicitly, suspect, and soon have their confidence shaken, and though good sense and fairness form their general characteristics, and promise, for desert, a sustained, if not very obtrusive advocacy, it may yet be owned, that the metaphor of a rock will not be at all too weak to express the probable strength of their support. Outside the House these gentlemen own generally for their leader the Committee of the National Association—a body of straight-forward, pure-minded, and highly-respected citizens, whose maxim would appear to be—

Fais ce que dois arrive que pourra.

Quiet, gentlemanly, family men, unused to public broils, they shrink from, and in that proportion invite, the antagonism that circumstances force on them, and in a war carried on *à l'outrance* feel happy—possessing giant powers to a pigmy's—if they can maintain safely the defensive. Moderate to tameness, their forbearance is attributed to timidity, and honest and unguarded to simplicity, their virtue is ascribed to folly. But time teaches; repeated danger warns; the unused vigor that might have ended annoyance, must now be applied to save existence, and the Committee, forced at last to the critical struggle, may rise to the daring of owning friends with gratitude, repelling foes with energy, and securing not only safety for themselves, but shame and discomfiture for their assailants.

The Bill's fate rests on them; they have truly an important part to play; but, most of all, it rests on that Parliamentary Leader whose fortunes are as much in the struggle as theirs. Wary—armed at all points—an eye that, under the guise of easy carelessness, sees the least glimpse of a weak point, and a vigor of throw that sends the ready dart with fatal accuracy straight to the uncovered spot, his warfare will not be dangerless. Let the General Practitioners support his amendments against the mal-content corporators, and Graham will make small work of Wakley. As well set a brawny pugilist against the accomplished master of the rapier. Graham's polished sarcasm will pierce the noisy mountebank through and through—were sensitiveness even as case hardened as conscience. But will the General Practitioners stand by the Minister? Will they reward the industry—the amenity—the good disposition—the readiness to concede—which, taken altogether, he has largely shown in their service, by giving him the gratification of passing his Bill at last? This is the problem yet to be solved. Our opinion is, that the General Practitioners, feeling that he has come into their terms quite as far as we may reasonably expect that, in *one* law any *successful* legislator can, will rally round him, and—a few details apart—triumphantly carry the Bill.

SHALL THE BILL BE LOST?

Is it advisable that the further consideration of the medical question be deferred to another session? Deliberate reflection says no! The present opportunity must not escape us. If the General Practititioners miss it, *years* (who knows how many?) will elapse ere a conjuncture so favourable will again present itself. On the one hand, we cannot hope that such an amount of professional talent and energy will a second time be brought into the field, and, on the other, beset, as the subject is, with difficulties of a peculiarly intricate and harassing nature, the minister might not be sorry to avail himself of a reasonably good excuse for postponing it *sine die*. We cannot, therefore, agree with our contemporary *The Times*, that the General Practititioners have everything to gain by delay. They have risk—very perilous risk to gain and nothing else. Should Sir J. Graham throw up the subject in despair, who else is likely to entertain it? or, should any other person, at a future period, introduce a measure of his own, what prospect is there that he would propose as much for us—much less *more—successfully?* Legislation is like architecture. A low fellow of bad character may destroy fifty measures but cannot build up one. There are those who think that by delay the General Practitioners will obtain still further concessions from the Minister. Anxious as we are to see full justice done to that important body, we must not conceal from them our opinion that they have obtained far more than we could have anticipated. Circumstances have been extremely favourable to them. The concessions already made to secure their acquiescence have roused into activity the Councils of the Colleges and of the Pharmaceutical Society. Sir J. Graham has exasperated them to satisfy us. If any division arise in the ranks of the General Practitioners, Sir James will be powerless for resistance; our cause will be lost in his weakness; and we must henceforth be content to remain in the unsatisfactory and equivocal position we at present occupy.

Another motive, which induces many to desire a postponement of the question, is a lingering hope that a reconciliation may yet be effected with the Council of the College of Surgeons, and that that refractory junto may yet be the seat of a General Practitioners' incorporation. Until the promulgation by the Council of their last ukase or manifesto, or whatever else that extraordinary production may be termed, we too had entertained the same hope, but with that document before us, the hope, and the desire too, has vanished. The recent Charter having been granted, in compliance with the 'humble petition' and 'earnest prayer' of the Council, it could not, we believe, be modified or repealed without the consent of every individual composing that Council. But their final decision is doubly complete. It makes accommodation as impossible on our sides as on theirs. It is no longer even desirable. Such persons would be a dead weight on any institution. With men who have endeavoured to stamp with inferiority a large class of their professional brethren, and who 'in the eye of the light, and in the face of the sun,' have avowed a gross abuse of faith and confidence, making for fees surgeons one day, whom for their own repute they deny to be surgeons the next—with such men we feel there never can be established an alliance either close, or honourable, or useful. Whatever we hold from them and value, we have held at their despite; and *now* we would be sorry to hold it on any other tenure. They cannot dispossess the General Practitioners of any corporate privileges they now enjoy as members of their College, neither can the law,—but what are their *privileges* that *gentlemen* and men of science should stand on them? The right of assuming a title, "Surgeon," which those who give it say we do not deserve—the use of the library, and an access, in common with the public generally, to the museum! These, with the addition of one or two courses of lectures delivered every year, constitute the sum total of corporate (?) privileges enjoyed during the present century by the members of the College, and for these they have paid about ten thousand pounds a year! Now what are such privileges compared with those proffered and the prospects opened by the proposed new College? Electing, like freemen and gentlemen, their own governing body, enjoying, *commanding*, a professional home, where, instead of being admitted as valets, they *abide* as masters—where they may assemble, and as contingencies arise, discuss matters relating either to science or medical politics, in this view, each member will be conscious that he counts this present state of things for something, and will feel prompted to seek the distinctions and places now laid open to a free exercise of his intellectual energies. A College school would soon spring up, the posts of examiners would be warmly contested—a museum, dedicated to every department of medicine and the collateral sciences, would early make its apparition—a library equally comprehensive would follow—prizes would be offered—professorships and scholarships endowed—and Medical Practitioners be brought in view of a new scientific era. A College of General Practitioners thus garrisoned, comprising as supporters the most important and numerous class of the profession, commanding ample resources wisely applied, having a Council elected on a free and representative principle—a College thus founded and conducted would, we conceive, attain ere long an eminent position in the estimation of the profession and the public. As its resources multiplied and its strength increased, it would gradually sap the foundations of those corporate establishments persisting in their old exclu-

sive systems, and on the occasion of any future remodelling, called for by advancing science, might become the corner-stone of a great National Faculty of Medicine. Physicians and pure Surgeons, who really seek an improvement of their institutions, on the liberal principles that suit the present day, will be as much interested in the success and grandeur of the New College as its own members. In the scientific elevation of so large a portion of our body the whole profession would rise.

TO THE PRACTITIONERS OF MEDICINE AND SURGERY IN THE PROVINCES.

Gentlemen,—In addressing you at this crisis, I am reluctantly stepping out from that retirement which for some time past I had imposed upon myself, in the expectation that the labours of the Committee of the National Association would terminate auspiciously for the profession; and that my humble services would not again be of use, either to support a good cause or to denounce a bad one; but recent demonstrations have rendered it a duty incumbent on every man, not utterly apathetic to the issue of these stirring events, to declare his opinions on the main questions involved in the Amended Bill of Medical Reform.

I feel impelled to adopt this proceeding, since I find that numerous individuals of intelligence and spirit have declared in favour of the new movement at the Freemasons' Tavern; and who, while condemning the Bill, betray a singular mental mystification, if not a total ignorance of its provisions. Some of these gentlemen formerly subscribed for the establishment of a new and independent college, and now, with ridiculous inconsistency, revoke, "in toto" their former declaration, —others of a more hesitating character, but with more judgment, would still rejoice to see a new college instituted, provided equal terms with the existing colleges of physicians and surgeons were guaranteed.

Now, gentlemen, the first order of individuals should never have joined the National Association, and will do as little credit to any new society, as they conferred on the old one. Of impressionable characters, energetic dispositions, and without fixed principles, they are obedient to every new impulse, and willingly submit their judgments to the caprice of the moment, or to the dictation of abler men. That such men are, we lament; but if they do harm the fault is ours.

It may be said, and has been said, that many of these individuals joined the National Association with the view of declaring contrary views to those entertained by the committee, and authorized by the majority of the members. But this a mere sophism: and, if true, was not the most honourable mode of conducting a political warfare. I am satisfied, however, that this class of individuals is a very small minority of the profession, and does not possess the regard or the sympathies of the well-informed, intelligent, and single-minded persons of whom the profession can so proudly boast.

Now, gentlemen, let me draw your attention to the provisions of the bill, which you hold in so much distrust, and which you have esteemed so thoroughly obnoxious as, on this account, to withdraw from the National Association. Even if you should be right, this act of petulance must incur its own punishment. Respecting *your* opinions, I trust that you will give mine a patient consideration.

Let us cast away all paltry and narrow-minded jealousies,—all the wretched instincts of malevolence and suspicion,—regard each other with a generous and amicable spirit, and repudiate those heartless recriminations, and selfish intrigues which, as unwise as they are dishonourable, can injure those only who expect to make them the instruments of their own advantage. I say this without reference to individuals or to parties:—for which side can declare itself blameless?

Various protests against the Bill have come up from the provinces, and among these, one the most important from the practitioners of Manchester, in which objections are strongly directed against the constitution of the joint board; by whose influence it is feared the college of general practitioners will be placed in a degraded position. The universal demand is for the admission of a suitable number of general practitioners to this board, and I am confident that the demand will be conceded if pressed in a proper spirit and manner, through the representations of the committee of the National Association, sustained by the zealous support of their members. I will affirm, what is an old truth, but which of late seems to have been strangely forgotten, that by such united support, medical men will find themselves in a much stronger position to command such concessions, than if they work in distinct associations, with divided resources and divided objects. Nothing but injury, defeat, and dishonour can attend divided councils.

The sole aim of my struggles has been to combine all reformers upon some common ground,—to remove asperities,—to induce mutual sacrifices, —to grasp some general principle of agreement, and work harmoniously together for its accomplishment. I cannot, therefore, regard the present dissension without alarm. Revert to experience, —the evidence of a few months,—what real advancement was made,—what tangible and specific object was pursued, until the National Association organised their thousands under the banner of a new and independent incorporation?

This was, from the first, their declared object, however doubted or gainsayed; and in the committee of the "Medical Protection Assembly," I and other gentlemen, for the sake of union, and with an urgent conviction of the necessity and propriety of the movement, advocated coalition on this principle. Difficulties afterwards arose between these bodies,—evoking personalities and mutual suspicions; nevertheless I still entertain the opinions I then enforced, and since the National Association is the only one that could ever embody the principle,—give it an active and progressive power, and promise an early and honourable termination of our struggles, I have subdued every private feeling, and now earnestly advocate co-operation with that body,—not to support what is bad in the Charter or the Bill, but to remedy both, and to obtain as much good, and to avert as much evil as may be within the power of an united, intelligent, and consistent body of men.

Much has been said and written about the degradation under which the General Practitioners will labour by the grant of a "liceat" by the Joint Board of Examiners. I cannot whine in so doleful a tone—I hold no such melancholy views,—I am not a political hypochondriac;—my imagination is not blackened by dismal anticipations of future oppression, nor by the steaming exhalations issuing from the caldron of party prejudices. How can the General Practitioners be degraded by what does not concern them? If after the General Practitioner had received his testimonial of qualification from his own college, he were compelled to submit to another Board of Physician-Surgeons for his licence to practice, there would, indeed, be a degradation, and the bitterest language of condemnation would be justified by the enormity of the offence.

The preliminary examination is simply a *student's examination*;—the liceat is, in reality, the mere testimonial of the proficiency of the *student*,—and is an awkward legal phrase, as incorrect as it is awkward, to express a very simple fact. If there be any degradation in the matter, it is the physicians and surgeons who are degraded, to whom such a preliminary office is assigned. There can be no question that the Board of Examiners of the College of General Practitioners is the *superior* Board. While, therefore, I contend that there is no degradation attaching to the General Practitioner by the constitution or powers of this Board, I would urge as a *right* that the General Practitioners should be equally represented there. I will not dilate upon the vast advantages which in my opinion will accrue to the profession and the public by the operation of this Board. I merely wish to show that the constitution of the Joint Board is not so highly objectionable a matter that we should on this account, insanely forego the numerous benefits we shall otherwise derive from the Bill and the Charter; and that the readiest mode of obtaining a change in its constitution, is by pressing our wishes in this respect upon the Committee of the National Association, and still retaining our adhesion to that body.

Again, serious objections have been alleged, and with justice, against certain provisions of the Bill, in reference to the title of Surgeon: but still much misapprehension exists even on this point.

It is most important that Provincial Practitioners more especially, should retain the title of surgeon, inasmuch as, by virtue of their title, they hold their appointments as *surgeons* to provincial hospitals and infirmaries, and with the loss of their title would lose their offices. I am, therefore, not at all surprised that you should express yourselves in an imperative tone in this respect; but, after all, does this Bill authorize any suspicion that the present surgeon will be deprived of his title? Certainly not: one clause of the Bill distinctly provides that every physician, surgeon, or apothecary, upon the payment of 5s. may be allowed to register as such, retaining by virtue of such registration all his previous privileges and immunities, in no wise affected by the provisions of the Bill. The surgeon will be in no worse position by the Bill, and certainly he will not quarrel and secede from the National Association, because it has not succeeded in placing him in a better! This body must try its influence again, backed by the unwavering, resolute, and enthusiastic remonstrances of its four thousand members. Nothing less than this will accomplish the end.

A question may be asked, whether as surgeons they will be permitted also to belong to the College of General Practitioners? I can certainly see no provision in the Bill to prevent this;—or even a double registration with double advantages! At all events, these points should be cleared up; and do you think you can effect this by dis-membering the National Association?

I grant too, the injustice of depriving the General Practitioners of the opportunity of holding the offices of surgeon and physician to our institutions, since the bye-laws of these Institutions specify such individuals as are qualified by these titles, which the future general practitioners will not possess. It is true that facilities are opened to the General Practitioner, ambitious of these honours, of qualifying himself in either respect after twelve years' practice, or when he has attained forty years of age: but this is not sufficient:—it is exclusive, and unfair, and places the badge of inferiority on the General Practitioners by legal enactment:—*it must be resisted!*

Gentlemen, your resistance will be vain and futile if you are dis-united. I implore you to consider your position well, before you listen to rash councils, or throw yourselves into an unavailing conflict. I know that when men's passions are once fairly embarked, we might as well attempt to arrest the falls of the Niagara with our five fingers as to check their impetuosity, yet I am not so gloomy a materialist as to suppose that you have not more intelligence than a rushing stream, and that you would thoughtlessly precipitate yourselves into an abyss, where, indeed, you might excite a great commotion, and much clamour, but where, certainly, you would be of no utility. We might stand by and wonder that there should be so much noise, and so very little advantage.

Do you suppose that you will ever obtain that reformation of the College of Surgeons, on an enlarged basis and equitable terms, which many of you desire? Never. Have you not struggled for it for thirty years, and what have you gained! A charter fraught with injury and degradation to the unprivileged members! For eighteen months you have denounced, and petitioned against this charter, and with what success? The council in their last letter treated your denunciations with contempt, and your petitions with official insolence. Have you then approached one step nearer to your wishes? You know that you have not, whatever weak and sanguine men may declare. And will you still pertinaciously continue a conflict which can bring on you nothing but disappointment, vexation, contumely and disgrace? There can be no doubt that a bold, ample, and fundamental reform of the College of Surgeons, by which this body might be constituted a College of Medicine and

Surgery, would be a most desirable object,—the evolution of a noble principle,—the accomplishment of our brightest hopes; but I firmly believe that that event was never more remote, than at this moment, and never more impracticable.

If we wish to effectuate any substantial good for the profession at this crisis, we must not be infatuated with metaphysical principles, nor shackled by ideal abstractions. The auspicious concurrence of circumstances,—the tendency of the moment must be seized, and our principles without being changed or abandoned, must condescend to forsake the character of naked abstractions, however graceful, and to clothe themselves after such a mode, as the evident and inevitable course of events may make necessary and wise.

We are foolishly told that a new College must be a *third estate*,—a degraded institution,—the last joint in the tail of medical bodies,—a corporation that can neither receive honour nor confer it,—in short, the lexicon of vituperation has been exhausted of all its ingenious and graphic phraseology to illustrate the coming birth. The profession can afford to laugh at these things. Those who affect to scorn the new College, must necessarily scorn also the respectability, talents, and acquirements of their professional brethren. It is an ignoble office, and if merit meet with its reward, will be duly repaid.

I have implicit confidence in the glorious potentialities which under the fostering influences of a new *Alma Mater* will be evoked from the professional mind. I have confidence in its seminal energies,—in its free emulative spirit,—in its expansive powers,—in its devotion to science,—in its intrinsic greatness, its destiny and its genius. The profession does not desire to *receive* honour from any institution;—it seeks only the opportunity of *conferring* celebrity. If it be assumed that no institution can be eminent or honourable that has not the prestige of great names, or that is not presided over by the Council of Twenty-one—then past experience is a nullity, genius a mere phantom,—its claims visionary, and the profession ignorant, incapable, and factious, is utterly unworthy of the grand object for which it strives. This would be a monstrous conclusion, and yet the unavoidable inference to be derived from those vapouring denunciations which have often rung in our ears, but perhaps were never intended to penetrate deeper, and which, intended to amuse the fancy, would have retired with a duly sensitive horror at the eye of reason. The profession is endowed both with genius and learning, and have within themselves the power of raising any new institution to the summit of scientific renown. The Council of Twenty-one have no monopoly of intellectual wealth.

Let us, gentlemen, abandon this degrading opinion of the professional mind; let us entertain a higher opinion of ourselves, and exhibit a self-reliance that should warrant for us the possession of the privileges to which we aspire. Strange to say, the General Practitioners themselves have enunciated these sentiments: but I hope for the future, that if they continue to hold such unworthy opinions—and little men must necessarily indulge little thoughts—they will be ashamed to vow them.

I must entreat you once more, gentlemen, to pause before you dissociate yourselves from the National Association, satisfied as I am, that nothing but defeat can track such a proceeding.

I have, Gentlemen, the honour to be,
Your sincere well-wisher,
GEORGE ROSS.

Kennington, June 3, 1845.

THE NEW INCORPORATION.

To the Editor of the "Medical Times."

SIR,—We beg to inclose, and place at your disposal, copies of petitions to the House of Commons, Sir J. Graham, and to the Council of the Royal College of Surgeons, which have each been signed by ninety six out of one hundred and ten members of the College resident in this town, and to state that of the fourteen remaining members who *have not signed*, eight have had the *fellowship given to them*, two refused and four from home.

Liverpool, June 3rd, 1845.

The Memorial Sheweth:—"That your Memorialists are all Members of the Royal College of Surgeons of England.—That your Memorialists indignantly and decidedly protest against the plan which you have proposed for the separate incorporation of the General Practitioners in a third and an inferior College.—Your Memorialists are of opinion that a College of Physicians and a College of Surgeons are amply sufficient for the protection and government of the Medical Profession in England and Wales, which they are strongly of opinion could easily be effected by advising her Majesty to grant a new supplementary Charter to the Royal College of Surgeons of England; but if corporate rights are not to be acquired in the College of Surgeons, they are decidedly of opinion that a College of perfect legal equality with that of the Royal College of Surgeons, should be incorporated upon the representative principle, by which the governing power of the College might reflect the character of the constituent body.—That your Memorialists consider chartered rights entitled to respect so far only as consistency and the rights of others are respected; and that your Memorialists have been, with many other Members of the College, unjustly excluded by the Council of the College from the lists of Fellows, and they consider that, by so very important a distinction, great injury has been done to them.—Your Memorialists, therefore, urge upon you a reconsideration of the measure you have proposed for the regulation of the Profession, and to adopt an amalgamation of the interests of the Profession into two Colleges only, and the Education for the Membership of each College to be of one uniform standard.—That your Memorialists present their individual thanks for the great interest you manifest towards the Profession."

The petition and remonstrance are precisely in the same spirit.

We are Sir, Yours, &c., &c.
JAMES COOPER,
41, St. Ann Street.
EDWARD BRADLEY,
Falkner Square.

MEETING OF CHEMISTS AND DRUGGISTS.

A numerous meeting of the Chemists and Druggists of London and its vicinity, was held at the Crown and Anchor Tavern, Strand, on Monday, the 2nd of June; Mr Morson, Vice-President of the Pharmaceutical Society, in the chair.

The Chairman stated that the meeting had been called by the Council of the Pharmaceutical Society, in consequence of the introduction of a clause into the Medical Bill now before parliament, which, if passed into law, would seriously affect the body which they represented, in common with every other Chemist and Druggist throughout the country. The clause to which he alluded was as follows:—

"And be it enacted, that every person who, after the passing of this Act, shall act or practise as an Apothecary in any part of England or Wales, without having been registered by the said Council of Health as a General Practitioner in Medicine, Surgery, and Midwifery, shall for every such offence forfeit and pay the sum of Twenty Pounds, to be applied to the use of the said College, and to be recovered by the said College by action of debt, in any of her Majesty's Courts of Record at Westminster."

The Pharmaceutical Society had been established with the two-fold object, of promoting the education of the Pharmaceutical Chemists of this country, and of protecting its members against any unjust encroachments upon their accustomed rights and privileges. The council had always borne these objects in view, and, although unwilling, by appealing to parliament, to impose any obstacles to the settlement of the question of Medical Reform, yet felt it their duty to offer a strenuous opposition to the Bill in its present form. In doing this, however, they were anxious to avoid any collision with the other branches of the medical profession; they had no wish to interfere in any way with the General Practitioners; and he trusted that the meeting would set an example, by the temperate manner in which they expressed themselves, and by the moderate and reasonable nature of their demands, that might be followed with advantage by their brethren throughout the country.

Mr. Jacob Bell moved the first resolution,

"That this Meeting observes with regret and apprehension the alterations recently made in the Bill for Regulating the Profession of Physic and Surgery now before Parliament, and feels bound to offer to the Bill, in its present state, the most strenuous opposition."

Mr. Bell observed that the present Bill was more objectionable than that of Mr. Hawes, as the definition "acting as an Apothecary" was omitted, and this might be interpreted so as to subject Chemists to constant penalties. It was not the wish nor the interest of Chemists to become Medical men. This would result in their place being supplied by another class, and they would ultimately be as badly off as the Apothecaries whose position he contended was by no means enviable. But the Chemist was often called upon to give an opinion as to the doses and properties of medicines; in some trifling cases they were applied to by the poor who could not get medical advice, and in cases of emergency, such as poisoning, it was their duty to administer an antidote, or use their endeavours to give relief. In all these cases they would be liable to a penalty by the proposed Bill. The dispensing of prescriptions was also according to recognised authorities and definitions the office of an Apothecary, although practically it was performed by Chemists. In opposing the introduction of the obnoxious clause, the society ought not to be considered to be acting in opposition to the Government. On the contrary, the principles for which they contended were precisely the same as those of Sir James Graham as expressed in Parliament. The proceedings of the Society would tend to promote the modification of the Bill in accordance with Sir James Graham's views, which had been superseded in the committee of the house. Mr. Bell trusted that the chemists would studiously avoid any political agitation, and come forward calmly and temperately, yet firmly, in support of the accustomed privileges of the body. If Sir James Graham had received the deputation, much trouble would have been spared; as this had not been the case, Mr. Bell hoped the chemists would set a good example to the medical profession by abstaining from those disputes and dissensions, which unfortunately were too prevalent among other bodies.

Mr. Squire, in seconding the resolution, expressed his concurrence in what had been stated by the previous speakers. He thought Sir James Graham could not fully approve of the Bill in its present form, as it was entirely different from that originally introduced by him.

Mr. Barclay spoke in favour of the resolution, which was carried unanimously.

Mr. Bartlett moved the second resolution—

"That the term 'acting or practising as an Apothecary,' occurring in clause 36 D, may be construed to apply to acts which are necessarily involved in the daily avocations of the Chemist and Druggist, and that this clause, besides placing on the Chemist a restriction alike unjust to him, and injurious to the public, would be a source of continual litigation."

That meeting, he said, had brought to his recollection the occasion when they had assembled in that room some years ago, for the purpose of opposing Mr. Hawes' Bill, and he trusted that the measures they might now deem it necessary to adopt, would be followed with the same satisfactory result as those pursued on the former occasion. The clause which had been read to them was quite as objectionable as any in Mr. Hawes' Bill, and he thought if it were passed into law it would be impossible for the Chemist and Druggist to carry on his business without being constantly liable to the penalty imposed by it. He trusted that the council would be supported by the great body of the Chemists throughout the country, in the appeal they were about to make to parliament.

Mr. D. B. Hanbury seconded the motion.

Mr. Toswill reminded the meeting of the annoyance to which they had been exposed in reference to the sale of spirit of wine, arising principally from the difficulty of determining in what cases the Chemist was liable to the penalty for selling that article; and he contended that the clause now in question would be quite as much a source of annoyance and litigation in reference to the sale of medicines generally.

Mr. John Bell proposed the next resolution—

"That the dispensing of prescriptions, and the preparation of medicines in general, is now, and has been for many years, principally performed in this country by the Chemists and Druggists; and that, in the Apothecaries' Act of 1815, a clause was introduced for the purpose of securing to the Chemist and Druggist the rights and privileges which he had previously enjoyed, and exempting him, in the exercise of his accustomed business, from the penalties imposed by that Act."

Mr. Gifford seconded the resolution, which was carried unanimously.

Mr. Thomas Herring moved—

"That Chemists and Druggists be recommended to petition Parliament not to pass the Bill."

He was glad to find that so able an advocate of their cause as Mr. Warburton had consented to present the petition to the House of Commons.

Mr. Leacher seconded the resolution.

Mr. Pigeou moved and Mr. M'Culloch seconded, a vote of thanks to Mr. Morson for his conduct this day.

The Chairman returned thanks.

The National Association have just issued a pamphlet of great importance. They respond to several objections taken to the amended Bill, explain their views of the expected action of the New College, and give in parallel columns a reprint of the two Bills, that last proposed, and the one now before the House. We may say *en passant* that we protest energetically against any such title as "Surgeon-Apothecary," that we will resist any proposal to make the Council of Health, a board exclusively of Government nominees, and that we are convinced that the Preliminary board should either have General Practitioners placed upon it—or be formed of non-Medical Professors entirely. Practically we know that there is no substantial difference on these points between the Association and ourselves, and we are quite certain that the less *new* points of discussion that are offered the profession the better. Leave well alone. The document is drawn up with considerable ability and is highly important. Gentlemen wishing a copy have but to forward their address to the secretaries. Those of our readers not members may adopt the opportunity to enrol themselves. There is no fee required.

No. 299 **SUMMARY.** June 14.

COURSE OF LECTURES ON THE THEORY AND PRACTICE OF MEDICINE.

Delivered by C. J. B. WILLIAMS, M.D., F.R.S., Professor of the Practice of Medicine, and of Clinical Medicine at University College.

The next nervous affection to be considered is hypochondriasis. There is some sort of difficulty in fixing its seat; it is referable to the stomach, the intestines, and the adjoining viscera, and yet all that can be learned by their examination falls far short of the patient's description; in fact in many instances the individual has the aspect of robust health, and yet from his description one would suppose every part of his body was diseased. There are all manner of uneasy sensations, distention of the hypochondria, pain in the stomach, indescribable sensation of knawing, anguish, agony, sinking, heat and cold in the upper part of the abdomen. The tongue is very often much furred, but in some instances it is pretty clean; the appetite varies remarkably, in many cases; there are often eructations of different kinds, and the bowels are often costive; various sensations are complained of in the head, which are referred to the occiput or to the temples; sometimes there is intolerance of light and giddiness; a feeling of pressure or squeezing of the head; the eyes are suffused and the vision often impaired, and the hearing also; all sorts of noises are complained of, singing or rushing, or cracking, and there appear to be images before the sight. These are sometimes very loudly complained of, and the patient being quite engrossed by them and a thousand other feelings, becomes irritable, crabbed, and disappointed; brooding over these symptoms, he shuns society and avoids all sorts of excitement; he is impressed by the idea that he is dying, or going mad. Yet in the midst of all this, if by good luck any event happens which attracts his attention strongly, and he is drawn into interesting conversation, all at once he becomes cheerful, and converses as if nothing at all was the matter. This could not be the case if he were suffering, even to a slight extent, from the sensations described. It is curious to see how intermittent these sensations are, the sufferers at times seeming to enjoy life more than other people. Some of the most entertaining persons in society have been hypochondriacs; Matthews the Comedian, Liston, and many other persons of note, who have caused a strong sensation in public, have been subject to great depression of spirits. There is a difference between hypochondriasis and melancholy; though the symptoms are intermittent and not to be considered as mental, yet it is quite clear the mind is not right, and there is a disposition to dwell on the morbid feelings with an extreme intensity, so as to make the individuals both morally as well as physically quite miserable, and irrational on the particular subject connected with their health, making them the laughing stock of the unfeeling, but objects of pity to those who consider how much they suffer in mind. These people read medical works with great avidity, and think they have every complaint of which they read. They are continually seeking for advice, and after having gone the round of the profession, they apply to quacks and old women, or any persons who can suggest any remedy to them. Hypochondriacal patients are sad trials to medical men.

In some points, hypochondriasis resembles hysteria; there is something in the nervous system both in relation to the inward feelings, the sensorial powers, and likewise with regard to the sensation itself which exaggerates real impressions; it is more in relation to sensation than to the other properties of the nervous system. The excito-motory function is not much affected in hypochondriasis. It differs, too, from hysteria, in affecting the old more than the young, and men more than women; but it resembles hysteria in affecting nervous subjects chiefly; those who have a highly developed nervous system. The class of symptoms that predominate, are those referred to the stomach or the intestines. These affections are aggravated by strong medicine. The patients always refer the seat of their sufferings to the abdomen and the hypochondria. Like hysteria, too, this affection is accompanied by little structural disease, but perhaps there is more visceral structural disorder than is generally supposed. The patients who are affected with hypochondriasis suffer for a long time, and by and by die of some other disease. The morbid anatomy of hypochondriasis has not been investigated with that degree of attention it would have, were it fatal. In those persons who have died, supposed to be affected with hypochondriasis, there have been found various affections of the intestinal canal; chronic affections, thickening of the coats of the stomach, the duodenum and the colon, independently of a low form of inflammatory affection passing on to structural disease; ecchymoses, and congestion of the liver and the abdominal vessels. The gall-bladder is remarkably enlarged in some cases, and in some, the colon has been found displaced, sometimes occupying the left side, and sometimes found in front of the liver. This is observed in a few cases only. Hæmorrhoidal disease to a considerable extent has been found in connection with hypochondriasis. There is also a very dilated state of the colon and rectum. The heart is sometimes slightly diseased; there is dilatation, and sometimes valvular lesions, and various other slight visceral lesions are occasionally met with. Little or no morbid change in the head has been found to occur in this disease.

The predisposing causes that seem to excite this affection are nervous, melancholic, or sanguine temperaments; the depressing passions have induced it, and a change from active life to solitude causes many persons to become hypochondriacal; disappointed ambition has often led to it, and the abuse of certain condiments, opium, tobacco, alcohol, and mercury, and strong purgatives have been followed by hypochondriacal symptoms. Continued indigestion, constipation, with the addition of mental worry, is very apt to be followed by it. Dyspepsia is another cause, and mental employments, which induce indigestion, will give a hypochondriacal turn. The most common cause is the stoppage of the hæmorrhoidal flux, where it has gone on for a number of years, and has then been arrested. The worst cases I know of have been connected with the stoppage of a discharge of blood from the rectum, arising from piles, prolapsus, or a swelling of that kind. It does not appear that indigestion is essential to the production of hypochondriasis, and we find every form of indigestion occur without it; but the remarkable manner in which the symptoms of hypochondriasis are aggravated by strong purgative medicines, does seem to point out that the alimentary canal is the especial seat of disease. The symptoms, however, connected with it are obviously nervous symptoms in the highest degree, and it would appear to be produced by a highly exalted and nervous sensibility of the abdomen; this being connected sometimes with one condition, and sometimes simply with increased sensibility. Many persons have attempted to consider the disease as one essentially connected with the digestive organs; others that the brain is the seat of hypochondriasis; and others again that its seat is in the nerves of the stomach and the ganglionic system. I have mentioned that the symptoms of this affection bear a very strong resemblance to hysteria in the number of the functions it affects, but that it differs from it chiefly in affecting the sensitive function, and that really appears to be its essential character; that there is an unduly developed power which may sometimes arise from moral causes acting on the brain, and that there are simultaneously deranging causes affecting the digestive organs in the manner I have explained, just the same as engrossing pursuits that cause persons to fast for a very long time, and thus to injure the stomach, and unduly excite and irritate the nervous system; and we must consider that the causes, that operate in this way may operate simultaneously on both. When a state of hypochondriasis is once produced, these symptoms may be excited by opposite states of the digestive organs whether full or empty, and whether they have or have not the power of digestion. Most of these symptoms have a remarkable connection with a congested state of the abdominal viscera, and this is the part we have chiefly to act upon. Sometimes a fit of gout will put an end to these sensations, and sometimes spontaneous eruptions will come out and give relief. I know one gentleman, who, in seeking relief, at last got hold of the water cure, and he fancies he was cured in that way. Sometimes serious diseases have been known to work a change. For instance, a patient has been attacked with violent diarrhœa which lasted a long time and threatened his life; he recovered and had no hypochondriasis afterwards. Again, an attack of fever has been followed by the removal of the symptoms. Jaundice, too, has had a similar effect. On the other hand, after a long continuance of this affection, organic, structural disease may result.

The prognosis of hypochondriasis is very much like that of hysteria. It is not at all a dangerous disease, and the patient is alarmed beyond what

is necessary—ridiculously alarmed; but it is a disease over which medicine seems to have little control. It is not to be cured by one remedy, but to be attacked by remedies suited to divert the mind, by frequent changes from time to time. In hypochondriasis, dyspepsia is the chief obstacle, and, in many recent cases, if you cure dyspepsia you may cure the hypochondriasis. If there are symptoms of gastric dyspepsia or congestion of the abdomen or viscera, and the patient is not weak, leeches to the epigastrium, or to the anus, will often give considerable relief; this should be in combination with low or light diet, and mild aperients, just as in gastritic or duodenal dyspepsia—light tonics, mineral acids, and metallic tonics, nitrate of silver, and so forth. In cases of great weakness, mineral waters and salines. It is of great advantage to give the patient change of scene, and employment enough to satisfy his morbid desire to be taking care of his health. Where the symptoms are combined with great weakness and a low state of the vascular system, the treatment is more difficult and less susceptible of relief. In these cases tonics are not borne; the nervous sensibility is too much exalted. In such cases, in by far the greater number of confirmed cases, the treatment should be principally palliative; mild purgatives, rhubarb, castor oil, sulphur, sulphate of potash, cream of tartar, in a diluted form, to ensure the evacuation of the abdomen, and to relieve the distressing sensations. Antacids are of use too; alum and magnesia, hydrocyanic acid, creosote, nitrate of bismuth, and aconite, are also useful. Cold drinks in some cases give great relief, and this may be by relieving the congestion or determination of blood to the parts. I have known cold water injections produce great relief when the disorder affected the lower part of the canal. In most cases the great object is to improve the state of the whole system by such means as will reduce nervous sensibility, and to improve the state of the circulation in the abdomen and in the head. Besides the medicinal means I have mentioned, if there be general plethora, the habit of cold sponging, or the use of the shower or plunge bath, alternated with friction, is of great use. A cold bath alternated with a vapour bath has been known to be of considerable efficacy. Active bodily exercise is more important than any remedy, and the patient should take as much riding or walking as his strength will bear. Horse-back exercise is the best, as it promotes the circulation in the abdomen, and enables the patient to take a greater amount of exercise than he can by walking. The game of cricket is also a very useful exercise. The great point in the treatment of these affections is to try to discipline the patient's mind, to induce him not to dwell too much on his complaints; that is not to be done by making light of them. There is no doubt that it is a species of monomania. The great object is to explain this to the patient, and to show him that there really is no mischief about which he should be distressed.

There is a disorder that can be scarcely dwelt on, namely *incubus*, or *nightmare*. There are distressing symptoms of oppression or weight referred to the chest, which come on during sleep; the patient wakes to a consciousness of this peculiarly distressing sensation, and although he is awake, and aware of the sensation, he has not the power of moving. He has not regained voluntary power; it is, in fact, a sort of partial sleep, a state of sleep accompanied by a strong impression on the sensitive nerves, but before voluntary motion is recovered. Sometimes there are various other uneasy sensations of which the mind is conscious during sleep. It may be that different kinds and sorts of dreams occurring during sleep, or when the person has some degree of consciousness, become converted, by imagination, into a monster which the imagination clothes with various forms; the idea of the nightmare, a monster horse squatting on the chest, and preventing the person from breathing. The late Dr. Gregory, of Edinburgh, dreamed that he was walking on burning coals, or on Mount Vesuvius or Ætna, and on waking, found that the real cause was that he had a bottle of hot water to his feet. The sensations he experienced during sleep operated on his imagination—which was still active—and became the subject of his dream. Cold feet are very often the cause of disturbed sleep and dreams, and a slight toothache or ear-ache, or any ache will become the cause of disturbed dreams. With regard to nightmare, many persons have indulged in superstitious notions, but the true explanation is to be found in the condition of the breathing which becomes oppressed, the involuntary motions being insufficient to keep it up; the circulation of the blood may thus become affected, and it may accumulate in the lungs, causing the sensation of dyspnœa, until the feeling of tightness in the chest, becoming more and more oppressive, haunts him with the idea of something pressing on his chest until he awakes, and then it vanishes. It is the return of volition that enables him to take a deep breath, and relieve the congestion of the lungs. The treatment will depend on the cause. It may be traced to crudities in the stomach, something disagreeing, and causing flatulency, and the patient after recovery breaks up a great deal of wind. Sometimes congestion is left behind, and then cupping between the shoulders may be requisite. Generally speaking, all that is necessary is to prevent those causes that disturb the respiration during sleep, taking care that the patient sleeps in such a posture that the breathing may be carried on as freely as possible.

Insanity.—We now come to the diseases of the mind. In these diseases, we have to consider the sensorial power as variously affected, and that very much in relation to the pathological conditions of the brain, the organ of these powers. Thus, for instance, the sensorial powers are exalted or excited by the slight forms of determination of blood, and by the early state of inflammation, which is accompanied by determination of blood, and when that excitement exceeds a certain amount, then they become disordered. For example, the sensorial impressions become so strong that they are painful, and are variously distorted and disturbed. The function of the brain, the organ of thought, becomes excited, and at last, after it passes the medium of moderate excitement, the impressions are hurried and too rapid to be reasonable—too rapid to keep pace with reality, and often, active as the faculties may be, they may become so active as to separate them from the external world; the imagination or conception under these circumstances, predominates over the reason and judgment, which are considered to be slow powers of the mind. The consequence of this over-excited state is that notions and ideas flow so fast, so strongly, as to overpower reflection and the memory of external objects, and consequently the powers of both mind and body are overruled by the impulses of thought and feeling of the world within. The ideas of the mind, self-originated by this over active state, are altogether derived from within, and are such as to overcome the impressions of the world without. It is curious how the ideas which are thus excited, are mixed up with bodily sensations or with recent mental impressions; and these mental impressions or bodily sensations often become the foundation of deep and lasting thought. In madness, which is nothing more than a waking dream, after delirium and phrenitis, the person complains of all sorts of horrible things, pricking of his head, of his being set on fire, fireworks, and a thousand other things. This is connected really with intense sensations. The same occurs in some forms of insanity, in a more marked and singular manner; and in chronic insanity, persons imagine they have no head; this may be connected with the common feeling of light headedness. Other persons imagine they have no body, and this is explained by the fact that the individual has lost the sensation of the body. There may be in other cases, no sensation on which the matter of insanity is founded, but the delusion may be altogether imaginary; or it may be connected with some former period of the life, or with the predominant passion, propensity, or affection. Conception under these circumstances is the source of the ruling ideas, and the manner in which insane persons illustrate their fancies is sometimes extremely ridiculous. Sometimes the one excitement may be of the more general kind, producing complete incoherency, in which case the utterance of the ruling thoughts becomes too rapid for expression, though a person who can ascertain the words can perceive portions of ideas, though mixed up in utter confusion, they being forced one on another with such intensity that they amount to nonsense. The same thing is observed in extreme forms of mania, constituting incoherent insanity.

Many lesions impair or destroy the sensorial functions; effusion and compression, softening, and the other results of advanced inflammation. Loss of the senses would be insufficient. If the memory alone is impaired, the external sense will keep the individual alive; but if the external sense also is destroyed with the memory, then this may constitute mania; on the other hand, if memory or sensation is impaired, the result is a diminution of the mental powers, and imbecility or idiocy may follow. In these cases, the individuals suffer various degrees of degradation. they become helpless, brutal, and bestial. This may be from no disease; it may be congenital, or it may arise from disease, or from atrophy of the brain, or weakness of the skull, or from hypertrophy, and over-growth of the head, causing ultimately compression of the brain.

COURSE OF LECTURES ON SKIN DISEASES.

By D. J. CORRIGAN M.D., Physician to the Whitworth, Hardwicke and Richmond Hospital, Lecturer in the Dublin School of Medicine, &c.

GENTLEMEN :—We, this evening, resume the subject of porrigo. I have been often told by medical men, that they have cured many cases of porrigo in their practice; and that they have had, from time to time, many cases of it under their care. Nothing is more common, than to hear persons boasting of having met with twenty cases of porrigo at a public dispensary on a morning, and it is not unusual to hear them speak of having cured the greater part of these. But I must say, gentlemen, that for my own part, I do not believe such stories; and I feel confident that they have been treating some of the various forms of impetigo, which they have regarded as porrigo. Genuine scald head is one of the most unmanageable diseases, which it can fall to your lot ever to become acquainted with. Do not believe those persons who tell you that they have cured it over and over again; they have done no such thing, nor believe them when they tell you, that it is a disease often to be met with: on the contrary, it is a disease of very great infrequency, and with the experience which I have had of it, I have never had under my care, at the same time, two patients affected with it, save once at the Whitworth Hospital. As an illustration of its great rarity, I may mention here, that some time since I was engaged making some inquiries connected with the Poor Law system; in following them up, I had occasion to go through the North Union Workhouse, and on carefully examining all the children in that institution, three or four hundred in number, I was unable to detect a single case of the disease, although cutaneous affections of every other kind were to be found among them. If any one circumstance could demonstrate its infrequency, I think that this does in a very remarkable manner.

To come to its treatment: on this head, I must confess that I can give you but scanty information, and to tell you the candid truth, I do not know a single article which possesses the power of curing it. To resume: I have heard—aye, and read too, stories innumerable of the cure of scald head, but, as I have remarked before, to these I give no credit; they were cures of something else, but certainly not of porrigo. Even in a case of this kind, nothing is easier for you to say, than that you have cured the patient. You can do this readily in a hospital, and mark him in the book, too, as "discharged cured." And so he is for the time. But keep this patient in the hospital for a fortnight or three weeks after this seeming cure, and what takes place? Does he continue cured? Not a bit of it. The pustules come out again as thickly as ever; and in a few days the disease is perfectly re-established. In my experience, I have never seen a person in the middle or upper

classes of society attacked with it, it has been invariably confined to paupers: its origin is unaccountable, and its treatment is equally hidden from us. I have heard persons speak of having cured it by ointments of iodurot of sulphur, and of this latter combined with iodide of potassium. It may be so, but I must confess, that though I have given both these forms a full and fair trial, I have never found any permanent advantage from their use. The French recommend, as applications to the scalp, in the first instance, ointments of pitch and tar, to remove the hair, bulbs and all. This is an unnecessarily cruel mode of removing the scabs, as a poultice, or any other emollient application answers equally well, and removes them without giving the patient pain. They also recommend a whole host of remedies after the scabs have come off. But the remedies which Alibert advises, are just as faulty as his classification of skin diseases. With him, every disease that attacks the head is tinea. No matter what it may be, it is nothing but tinea. This mode of nomenclature is about as rational as if a person jumbled together all the diseases which the lungs, or any other of the viscera, are liable to, and called them all by one common patronymic. The only remedy which I can recommend with any hope of its proving successful in your hands, is muriatic acid. This I was led to employ from reflection. Knowing that lime entered largely into the composition of the solid matter forming the disease, in the shape of carbonate and phosphate, I thought that the action of the acid upon that matter might be attended with beneficial results. This I have tried but in one instance; under its use the patient got well, and continued so for a fortnight or three weeks after, when he left the hospital. He never returned, so that I have reason to think, from this latter negative proof, that he remained permanently cured. Yet, allowing that he were, from the successful issue of a single case, I could not recommend it to you as a remedy capable of curing scald head; however, under the circumstances, I lay it before you as a remedy claiming a greater share of merit than any other with which I am acquainted. The manner of using it is as follows. remove the incrustations from the scalp by means of a poultice, and over the red surface rub every night and morning a small portion of an ointment or pomatum, composed of ℥j of muriatic acid, to an ounce of spermaceti ointment. I must again confess my ignorance of any means of cure beyond this, and, in addition, can only refer you to some of those remedies which have been vaunted as cures for it.

In making the foregoing remarks on porrigo, I take a view of the matter quite different from that of systematic writers; my opinion with regard to its non-contagiousness is quite at variance with that generally entertained. However, though my views may possess the seeming disadvantage of singularity, and of being unsupported by other authority, you may rely upon them as deductions lawfully drawn from an attentive experience of the disease.

The next class of skin diseases which claims our attention is that of papulæ, or pimples. A papula is an elevation of the cuticle not containing fluid, and ending in desquamation. Of this class there are but two varieties, namely, lichen and prurigo; lichen is a papular eruption, attacking for the most part children at the breast, and, I am sure, is familiar to all of you under the name of red-gum. Of this affection there are as usual several varieties, to show off the cleverness of our authors. But if you content yourself with keeping in mind the definition of a papular disease, and take care not to confound lichen with prurigo, you will be in possession of as much knowledge of the former as you need wish to have; recollect that it generally attacks children of a tender age, and that it consists of an eruption of papulæ of various colours, (which latter circumstance has been taken advantage of to raise divisions between the whole family of lichen), and that these papulæ always end in disquamation. There is a variety of lichen which appears in adults on the approach of warm weather. It comes out on the loins, on the buttocks, and along the calves of the legs. It appears thickest on those who seldom, if ever, clear their skin by the use of the warm bath. This variety of lichen is very often a source of uneasiness to persons afflicted with it, as, after it has desquamated, the appearance of the skin would lead one to suppose that it depended upon secondary syphilis; an attention to the history of the case will decide this, and if you wait for a few days, you will find this colour of the skin altogether disappearing.

There is another variety of it named L. urticus, or Tropicus, affecting as the name denotes, persons residing in tropical climates. I have never seen it and know nothing of it, consequently I cannot give you any information upon it. Along with the two orders of papulæ which I have laid down, some writers add a third named strophulus. This is nothing more nor less than lichen, and as we are not particularly fond of hair-splitting distinctions, why we shall do very well with our own arrangement.—lichen being a disease of no importance, we shall say no more about it, but proceed at once to prurigo.

This is a disease which you cannot enter into any hospital without seeing half a dozen cases of. You find it generally in old persons whose constitution has been broken down by want, intemperance, mercury, or the effects of disease. It appears in an intermittent form. The patient on getting into bed at night is seized with an intolerable itching, which drives him or her almost mad. During this paroxysm, which disappears towards morning, the nails are freely used in scratching, and the patient presents at our morning visit, the appearance so admirably pourtrayed in this drawing, (it was one of P. senilis attacking the chest and back with a pediculus, drawn from a magnified representation of the vermin). Here the papulæ which had come out on the previous evening, accompanied with intense itching, are seen like so many stigmata or petechiæ; you never find any extravasation about them. Their likeness to stigmata is caused in this way; the top of each papula has been torn off by the scratching, and a minute drop of blood is seen occupying its place, while patches of skin, not covered with papulæ, but stripped of cuticle are seen interspersed, with bloody traces of the rough usage received at the hands of their owner. In all these cases you will find the eruption accompanied by a plentiful crop of pediculi. In such cases, you must improve the patient's habit of body by good animal food, tonics, and the use of every thing which will nourish, but not stimulate. In addition to this, great relief will be derived from the use of a lotion of corrosive sublimate in the proportion of two grains to an ounce of distilled water. This lotion, applied over the affected surface, gives more relief from the distressing itching than any other remedy with which I am acquainted. Here lotions of lead are not of the least service. There is a form of prurigo attending jaundice when the itching also is intolerable, so much so as to place the patient beyond all self-control.

I have frequently found gloves worn constantly by persons, to prevent themselves if possible from injury by indulging in their irresistible temptation. In this form of prurigo I have witnessed very material alleviation of suffering from the use of lotions of warm vinegar. There are some local varieties of the affection, for instance, when it attacks the anus, and the pudendum muliebre. When it attacks the anus it is in general symptomatic of ascarides, which should be sought after and removed. Here the irritation at the anus obeys a law which seems to hold good throughout the whole body, namely, that when a mucous canal is exposed to irritation of any kind, its outlet is generally that portion of it which suffers the most pain. Instances of this are to be met with in irritation of the bladder, arising from the presence of a calculus, when the greatest pain is felt at the extremity of the glans penis; we find the alæ nasi swollen and painful in derangements of the stomach and alimentary canal, which symptoms are by the vulgar set down to the account of worms, though very often dependent upon causes widely different. In p. pudendi. muliebris, the irritation to which the patient is exposed is dreadful beyond all conception, it is so severe as frequently to leave the victims of it quite beside themselves. And to such an extent has it sometimes wrought upon females of nice feeling, as to have driven them to the commission of suicide. Some first become nymphomaniacal, and from this state sink into one of perfect dementia. The sufferings of the unfortunate female labouring under this disease, are such, as you could not conceive it possible for any human being to endure. The consequence is that she becomes secluded from all society, and brooding over her wretched fate in solitude, indulges more and more in this dangerous temptation, which, it is but justice to her to add, she cannot withstand. I once knew a lady affected with it, and her sufferings were awful beyond the power of exaggeration. This form of prurigo is generally symptomatic of malignant disease of the neck or body of the uterus, but more often of the former. When it arises as an idiopathic disease, relief will be procured, generally speaking, from the use of the corrosive sublimate lotion. The French treat this form of it by means of the vapour of sulphur. For this purpose the patient is put into a flannel bag, similar to those you have seen at the Whitworth, kept in shape by one or two hoops. The patient gets into this, which is secured about her hips. A saucer containing some lighted sulphur is placed underneath and within this, and the sulphureous vapours are allowed to play around the lower part of the pelvis. By this means you will very often cure your patients, or give them very material relief, when it is uncomplicated with structural disease of the uterus. When it accompanies the latter, you must endeavour to palliate it, while at the same time you direct your endeavours to remove if possible the disease which has given rise to it.

Prurigo, when it appears in persons late in life or of a broken-down constitution, is seldom if ever cured. The only thing you can do is to palliate the troublesome itching; for this purpose some have recommend sulphuric acid, largely diluted with water, as a lotion to the affected parts. Bateman speaks highly of oil of turpentine, diluted with oil of almonds. But to all these I should be inclined to prefer the corrosive sublimate lotion as being more certainly beneficial. Prior to the general use of linen as an inner garment, this disease prevailed almost universally; and so great was the exhaustion produced by its long continuance, that we are told, that some of the most celebrated characters of antiquity fell victims to its irritation.

The next division of skin diseases which come under our notice is that of scales or squamæ. This contains the following orders, viz:—

Psoriasis, Lepra, Pityriasis, and Icthyosis.

Of these, only the two first ever happen in anything like an acute form. What I mean by this is, that lepra and psoriasis are not fully formed for three weeks or so. A person in these diseases may complain of slight feverish indisposition for the above length of time, and minute, and perhaps numerous, stigmata make their appearance on different parts of the body. These stigmata coalesce, become, in a short time, changed into so many layers of dried cuticle, which are raised above the surrounding skin, unattended with any fluid secretion, falling off after a time, and leaving the skin underneath red and irritable, and capable of reproducing the same scale. The eruption of lepra and psoriasis may, with more propriety, be said to be subacute rather than acute, as this latter expression would be apt to lead us into the erroneous belief that these run their course like skin diseases, such as small-pox, which are really acute. A distinction has been made between lepra and psoriasis, on the ground, that the scab in the former is above the level of the skin, and in the latter, upon the level of it. Those who make this distinction, add further, that lepra may be known by a central depression in each scaly patch. In my opinion, this distinction is an unnecessary one, and one which you should not attend to. It does no good, but a great deal of harm, to perplex the study of the disease by such distinctions. If you want to make psoriasis of lepra, all you have to do is to remove the scale from the latter, and the one disorder passes into the other. (Exhibiting a plate)—Here you perceive, in this subject, both forms of disease, (as described in books,) accurately existing. On the upper part of the thigh, you

have genuine lepra, and below the knee you have genuine psoriasis. Take away the scab from the leprous patch upon the thigh, and you have true psoriasis. Do not mind making divisions of diseases, which really are one and the same; there is no use doing it, when neither the anatomy of the disease, nor microscopic investigation, confirms or supports these fanciful distinctions. In the observations which I am about to make, you are to understand, that when I speak of psoriasis, lepra also is included. Of this disease there are a great many varieties, named after the forms it assumes. You may find it in circular patches, as in these drawings, or you may find it progressing in the manner I have spoken of in porrigo, getting well in the centre, and proceeding outward towards the circumference of the patches. At other times, you may see it describing all sorts of figures on the parts it attacks, as in this plate, forming the variety called P. gyrata; not that these varieties, or a knowledge of them, enable you to treat the disease more successfully, but that an account of them may be interesting to such of you as are curious upon the subject. There is another variety of it, attacking the scalp, and which you might confound with eczema. In the latter, the scabs are thin, and come off quickly; when you remove them, the vesicles form again beneath, dry up, form a scale which comes off, while, in psoriasis the scale is thicker, and when you remove it, you never find it reproduced by vesicles. Psoriasis may appear in patches covering large portions of the body, or in minute spots only, copiously scattered all over the body. This latter form of it bears a great resemblance to lepra, as pourtrayed in these drawings; this is only natural, as both are identical. This is the P. guttata of writers. This variety you should be acquainted with, not on its own account, as much as for the sake of knowing that it does assume such a form.

Another variety is that called P. palmaria, where, as the name implies, the hands are the parts affected. Here the skin covering the palms of the hands becomes thickened, the parts underneath crack, and bleed; and thus a very painful form of it is produced. The wrist, in these cases, sometimes becomes affected in the same manner, covered with *rhagades*, and bleeding. Another form of it sometimes attacks the lip—oftenest the under—frequently both. The lips become thickened and puckered, but in consequence of the parts being constantly kept more or less moist, scales do not form here as perfectly as in other situations. Psoriasis may appear, not as an idiopathic disease, but produced in consequence of some irritation applied to particular parts; thus, the hands of washerwomen, from the use of soda and other alkaline irritants, which their labour obliges them to handle, become affected with a form of it called P. inveterata. Here the scab is thrown off—the skin beneath becomes inflamed, and fissured, and bleeds, and finally, a very painful variety of it is produced. Psoriasis is of consequence, not so much on its own account, as that it may be confounded with a form of venereal disease, which, from its taking on the characters of the former, has been called venereal psoriasis. But there are two marks which will invariably set you right in making the distinction between the venereal and non-venereal variety, and one or other of which is never absent from the syphilitic psoriasis. These are, firstly, a copper-coloured hue of skin, which always attends the scaling off of each patch of syphilitic psoriasis; and secondly, the scales of the venereal variety are, in every instance, formed from papulæ, while in idiopathic psoriasis this never occurs. These papulæ may frequently be recognised among the scabs, and we also find pustules very frequently interspersed, being merely the results of the same cause which, in the first instance, produced the papulæ, so that you have at once, in the same person, perfect examples of papular, scaly, and pustular secondary syphilis.

On Monday evening we shall resume this subject.

APOTHECARIES' HALL.—The following gentlemen were admitted Licentiates on the 29th of May, 1845:—William Edward Stewart, Richard King, William Wadham, Chas. Brightley Prentice.

CLINICAL LECTURES ON MEDICINE

Delivered at the Meath Hospital,

By ROB. J. GRAVES, M.D., M.R.I.A., &c.

Fever—Discharge of Blood per Anum—Treatment by Acetate of Lead and Opium—Action of Acetate of Lead on the Evacuations, Bronchitis—Extraordinary Quickness of the Pulse—Fever—Tympanitis—Diarrhœa—Dr. Bardsley's treatment of Diarrhœa by Acetate of Lead—Chronic Hoarseness and Laryngeal Cough—Treatment by Mercury—Diagnosis of Idiopathic Laryngitis, and Laryngitis connected with Phthisis—Sub-acute Laryngitis—Suppression of the Catamenia—Ascites—Hæmatemesis—Treatment by Chalybeates—Cold—Turpentine—Ipecacuanha—Rheumatic Arthritis complicated with Bronchitis—Treatment of Iritis—by Mercury—by Turpentine.

WE shall take up to-day the case of Sarah O'Neil. She had, you will recollect, on the 24th of Feb. a considerable discharge of blood by stool, and though it is not proper to interfere with such discharges *in limine*, and when they come on about the critical period, still her weakness, with her peculiar constitutional tendency at that period to sanguineous fluxes, induced me to prescribe the acetate of lead and opium, directing that it should be repeated or stopped, according to the circumstances of the case. On the evening of the 24th, her pulse was one hundred and sixty, small, but distinct; during the night she had another copious discharge of blood from the bowels. She was ordered to take, every third hour, two grains of the acetate of lead, with five drops of the tincture of opium, made up as before into a draught, and to continue her wine. On the 26th, the report states as follows: "patient pale and prostrated, action of the heart still violent and exceedingly rapid, respiration quick and laboured, forty-four in a minute; pulse two hundred; has had two discharges from the bowels, consisting chiefly of blood. She has taken twelve ounces of wine since yesterday." She was ordered to have wine *ad libitum*, and the following pill was prescribed to be taken every hour to the fourth time, and afterwards as occasion required:—opium in powder, half a grain, acetate of lead, three grains. In the evening the pulse, when counted, was found to be two hundred and four.

Next day, an improvement of her symptoms appeared, contrary to all expectation. Mr. Nalty, who paid particular attention to the case, had continued the acetate of lead and opium, increasing gradually the quantity of the latter, and watching the effects of each successive dose. Towards evening, the hæmorrhage appeared to be abated, but as this might only be a temporary check, he continued the draughts at greater intervals, only suspending their use when all symptoms of danger seemed to be completely removed. She slept at times during the night, regained some of her strength, and the pallor of hæmorrhage was again replaced by the flush of fever. Her pulse had, however, fallen considerably; when examined in the morning, it was only one hundred and twenty. She had also a very copious alvine discharge, unmixed with blood, which in such cases is always to be regarded as a very favourable circumstance. In cases of discharge of blood from the stomach or bowels, where means have been taken to check the hæmorrhagic tendency, the bleeding will often appear to stop, and you will be inclined to think all danger over: but there is always a source of error connected with such cases. In hæmorrhage from the bowels, you can never be sure that the bleeding has ceased until the patient passes an evacuation unmixed with blood; for the bleeding, though apparently arrested, may be going on internally. Hence the appearance of a natural alvine discharge is always a source of certainty with respect to the state of the bowels, and informs the physician that his means have been successful.

In this case however, there may be still one source of error. The discharges which this young woman has passed are all of a slate colour. How is this produced? It arises from the mucus of the bowels being coloured by the acetate of lead. Acetate of lead, when used in large quantities for any considerable time, invariably blackens the evacuations. Here the colour is merely dark grey or slate colour, for the quantity she has taken is small. You can however, always distinguish this tinged mucus among the natural discharges, the colour being mixed only, and not blended with the latter, as it is with the former. But if the evacuations be of a dark colour, such as is seen in cases where blood has been effused into the intestinal tube, and changed by the acid juices of the canal into a dark coffee ground or nearly inky appearance, it becomes very difficult to distinguish this from the tinge given by acetate of lead, unless you are accustomed to it. In the present case there does not seem to be any thing more than a tinging of acetate of lead, nor have we been able to trace any thing like coagulated blood in the stools. I may observe here, that a considerable degree of error has existed with respect to a peculiar greenish discharge from the bowels, composed of morbid matter secreted by the diseased mucous membrane. I was the first person who pointed out this fact in the fourth vol. of the Dublin Hospital Reports. All practitioners before me, and among the rest Dr. Cheyne, attributed this to an effusion of morbid bile. This error I regret to say is still prevalent; you will hear medical men, when they meet with this discharge in children, say that it is the result of a morbid secretion of bile, and that the child requires calomel purgatives to carry it off. It is true that morbid bile may irritate the intestinal mucous membrane so as to cause an effusion of this green secretion, but still this is not bile. Bile, when secreted in large quantities is never green; it may present a lighter shade of yellow, but it is never green. This secretion comes from the surface of the small intestines, and is generally the result of irritation. What is the consequence of inflammation in other mucous tissues, in the eye for instance, or in the urethra? Do we not see the mucus assume a yellowish and even a greenish colour? The discharge from an irritated mucous membrane may assume all shades from a pale white to a yellow or green. I dwell on this, chiefly to point out the gross error of looking upon the discharges from the irritated surface of the intestines in children as consisting of morbid bile. It is not depraved bile, neither is it to be removed by calomel or strong mercurial purgatives. It is by changing the diet, keeping the child warmly clothed, and prescribing small doses of hydrarg. c. cretâ with Dover's powder, that this diseased secretion is to be checked. What does calomel do? It frequently produces exactly the same state of the digestive tube. You will have in a patient taking calomel, a copious secretion from the intestines of a deep green colour, resembling chopped spinach, accompanied with pain of the bowels and other symptoms of irritation, shewing the source from which the discharge proceeds.

But to return to this woman's case.—Yesterday her face was flushed, her breathing still laboured, and she coughed occasionally. On examining the chest, we found evidences of the existence of bronchitis; we have, therefore, ordered her to take the decoction of polygala, with carbonate of ammonia. I had almost forgotten to observe, that since the cessation of the intestinal hæmorrhage, her pulse has fallen considerably, and is at present no more than 120.

One of the most remarkable circumstances in this case is the extraordinary quickness of the pulse. On the 24th, it was 150—on the 25th, 160—on the 26th, it was nearly 200, and on the evening of the same day, it was as high as 240. I counted seventeen distinct beats in five seconds, and what was equally remarkable, the pulsations of the artery were not fluttering, intermittent, nor running into each other. I could plainly feel each beat, and though the pulse felt extremely small, still it was not as weak as one would be led to imagine. This is the highest pulse I have ever been able to count in a satisfactory manner, for generally speaking, when it goes beyond 160, it becomes difficult to ascertain its number exactly. In this case, however, it was as distinct as if it were only 160.

I need not observe here, that in cases of hæmor-

rhage, where the discharge threatens to become excessive, and where the patient has been prostrated by previous fever, you should endeavour to arrest the flow of blood, by means of acetate of lead, opium, and wine. These, which are the only means we possess of combatting a most threatening symptom, we have employed in various forms, and with all due diligence, and for the present, at least, we have succeeded in rescuing her from death: but her condition is still exceedingly precarious, and we have, I fear, just grounds to be apprehensive of an unfavorable result. She is, it is true, in the prime of life; her constitution has been originally good; she retains some degree of muscular strength; her mind is still collected, and her fever somewhat diminished; but where the pulse continues so rapid, and where the respiration is so quick and laboured, there is much to fear.

In the case of another young woman named Jones, who is now convalescent, tympanitis commenced nearly about the same period of fever, and under similar circumstances; but here nature attempted the relief of the abdominal congestion, not by an effusion of blood, but by means of a copious watery diarrhœa. She passed enormous quantities of this secretion, which appeared to consist of aqueous fluid, mixed with coagulated and shreddy mucus, so as to resemble decayed vegetable matter, which had been chopped small and left to macerate in water, until it became intimately mixed up with it. Now, as in the former case there was danger from excess of hæmorrhage, so, in this case, we had, from the persistence of the diarrhœa, reason to think that the patient would be run down by inordinate secretion. We, therefore, after the lapse of a few days, attempted to check it by the use of acetate of lead and opium, with wine, and were so fortunate as to succeed completely. We gave her draughts, composed of acetate of lead and tincture of opium in camphor mixture, two grains of the acetate of lead, with five drops of laudanum in each draught. Of these she took five the first day, four the second, and three the third. On the evening of the third day the secretion from the bowels was so much arrested, that it was deemed unnecessary to continue them any longer. Their use has not been followed by any unfavorable result; the patient has been improving rapidly ever since, and is now able to sit up.

Since I received a communication from Dr. Bardsley, recommending the trial of acetate of lead in that form of diarrhœa which comes on towards the termination of fever, and generally ends in ulceration of the Peyerian glands, I have made several clinical experiments with the view of ascertaining the powers of this remedy. I have found it exceedingly useful in controlling superabundant secretion in numerous instances. I have experienced the best effects from its employment, not only in the diarrhœa which accompanies ulceration of the mucous glands, but also in that species of diarrhœa which occurs at an earlier period of fever, and by means of which nature attempts the relief of intestinal congestion. Of its great value in the treatment of cholera I have already spoken; indeed, I do not know of any remedy by which inordinate fluxes from the bowels, whatever may be their nature, are so efficiently treated. The same remarks will apply to super-secretion from the lungs. In cases of phthisis attended with such copious secretion as to threaten suffocation, it is very beneficial: its effects are equally remarkable in chronic bronchitis with copious expectoration, and you are all aware of the great efficacy it possesses in checking hœmoptysis. I have been in the habit of prescribing it in combination with laudanum and wine vinegar; the latter I have added on the recommendation of Dr. Thomson, of London.

With respect to the case of the boy Francis Thorpe, to which I alluded in my last lecture, and who has been for a long time labouring under chronic hoarseness with laryngeal cough, I may observe, *en passant*, that he presents to-day some symptoms of improvement. You recollect, I attempted to remove the irritation of the larynx and fauces by the use of iodine inhalations, touching the throat with a solution of sulphate of copper, and by exciting counter-irritation over the whole anterior surface of the neck by means of croton oil liniment. Having found these measures insufficient, I had recourse in the next place to the internal use of mercury, so as to affect the system, and to inhalations of hydragyrum cum creta. My object here was to bring on salivation at once, for in many cases of chronic laryngitis, the patients experience a sudden relief of the symptoms as soon as the mouth becomes affected. In this case the same favourable result has, to a certain extent, followed mercurialization. By making some exertion, the boy can now speak with a tolerably clear and audible voice, his cough is also diminished, and I have no doubt but that by a perseverance in the same measures we shall effect a cure.* There was some doubt with respect to the safety of giving mercury in this case, on account of the long continuance of laryngeal cough, and the suspicion of the existence of phthisis in its first stage; but as the boy had no fever, and as there were none of the stethoscopic phenomena of phthisis present, I determined on giving it a trial as the last but most powerful resource we possess in such emergencies.

This, Gentlemen, is a most important point in practice. You meet a case where hoarseness and laryngeal cough have continued for weeks or even months, where various remedies have been tried in vain, and where although the general health of the patient was not originally much affected, yet his loss of flesh and his pale looks betray at length unequivocal tokens of suffering—in such a state of things, everything will depend on ascertaining whether the laryngitis is a mere symptom, a consequence of scrofulous disease of the lungs, of phthisis in fact, or whether it is the sole and original affection. If the latter, a proper local treatment, mercurial pills and mercurial inhalation, will cure the disease. If the former, these means will prove injurious by accelerating the progress of the scrofulous development. The diagnosis, gentlemen, is, I confess, often uncertain, for the obstruction which exists in chronic laryngitis to the quick entrance of air into the lungs, renders the stethoscopic phenomena of co-existing pulmonary disease very uncertain; your chief guide will the date of the laryngeal symptoms; if violent and intense in the very beginning of the disease, then they are probably the cause, and not the effect.

There is a case in the fever ward, in which respiration is accompanied by a very curious modification of sound, produced by the passage of the air through the larynx, and resembling a loud ronchus. I was at first quite certain that this noise was made by the nose and soft palate—in fact, that it was ordinary snoring; but as the same sound continued when the man lay awake, I was induced to examine it more accurately, and found by the stethoscope that its seat was not in the soft palate, but about the inferior opening of the glottis. I cannot exactly say on what this depends; we cannot discover any affection of the throat or fauces. The mucous membrane is of the natural colour, and there is no lymphy or purulent secretion to be seen on any part of its surface. Still there may be some irritation of the larynx, or some alteration in its secretion. The mucous membrane of the larynx and bronchial tubes is very often affected in fever: it becomes dry, and its secretion undergoes a species of morbid change. It is quite natural to expect heat and dryness of the bronchial mucous membrane in fever; its secretions also participate in the morbid alterations which take place in the skin and intestinal mucous membrane. You will also frequently observe that in fever cases, where dry bronchial *rales* and difficult expectoration occur, an augmentation of the cutaneous transpiration will be followed by sudden relief of the pulmonary symptoms, showing the intimate sympathetic relation which exists between these two tissues. With respect to the present case we know very little of it. The man came into the hospital in the advanced stage of maculated fever, for which he is still under treatment.

* This treatment was persevered in, and the boy left the hospital in the course of a few weeks perfectly cured.

I have ordered his throat to be rubbed with mercurial ointment, combined with extract of belladonna, and then covered with warm flannel; I have also directed that he should be removed into a more comfortable room. I have prescribed belladonna with mercury, under the presumption that there may be some subacute inflammation present, as well as, perhaps, some tendency in the muscles of the larynx to spasmodic action; for both these the remedy employed is well adapted. We cannot at present say any more on this case; a few days however will clear up the matter.* I may observe that I do not, as far as I can judge, anticipate any dangerous consequences. The disease has remained stationary for three days, and does not appear to threaten an unfavourable result. Still as it is an anomalous symptom, and occurring in an organ whose affections often take a very unexpected turn, it will be necessary to be on the watch, and attend carefully to the condition of the patient.

Let us pass now to the case of Teresa Pender, who was admitted yesterday evening, and whose examination this morning affords matter for consideration. This young woman has been labouring for the last ten months under suppression of the menses, and it is probable that the chief part of the various affections of which she complains may be traced to this source. Within the last six months, swelling and infarction of the belly commenced, and these symptoms were gradually succeeded by ascites. She has been for a considerable period subject to all those harassing abdominal symptoms which so frequently accompany suppression of the catamenia; she has suffered repeatedly from nausea, vomiting, colic pains and costiveness. Her belly is now greatly tumefied, she has swelling of the lower extremities, and more or less general anasarca.

Within the last two days a new and serious affection has been added to the list of her complaints, namely, hæmatemesis, and it is to this symptom in particular that I wish to call your attention, as it may have a very important bearing on her present condition. It is true that the history of the case, while it points out many circumstances indicating the existence of important visceral disease, still leaves a slight gleam of hope. The probable existence of internal disease, the gradual appearance of the ascites and anasarca, the sallow greenish hue of countenance, and look of suffering so expressive of long continued visceral derangement—these circumstances, combined with the vomiting of blood, form a very serious catalogue of evils calculated to render her case extremely doubtful, and requiring all the resources of medical skill for its treatment. The only chance which still remains, and throws a gleam of hope on the unpromising nature of her complaint, is that she has hæmatemesis, and that this hæmatemesis may be connected with the suppression of the catamenia. You are all aware that vomiting of blood is sometimes vicarious with the uterine discharge in cases of suppressed menstruation, and this it is to be hoped is the case in the present instance. On the other hand, if the vomiting of blood were merely connected with the ascites, it would be an extremely unfavourable symptom; I have never seen a patient, except one, recover under such circumstances. This was a boy who was a patient at the Meath Hospital about ten years ago; he had ascites, during the course of which he was attacked with vomiting of blood; this, however, was checked without much difficulty, and he ultimately recovered.

Now as to our mode of treatment. This young woman, as you may have observed, is very much debilitated, her pulse is quick, but it is also small and weak; she has a cool skin, and there is no tenderness of the epigastrium; I have therefore given up all idea of treating the case antiphlogistically, and intend to treat it as a case of passive hæmorrhage arising from a congested state of the gastro-intestinal mucous membrane, connected with organic disease of a chronic character, and not with active inflammation. I have ordered

* This case proved to be one of subacute laryngitis, and yielded to the remedies employed.

a variety of remedies in succession, one to be employed if the other fails; for in cases like this it too often happens that all calculations drawn from previous experience are found to be vain, and our only chance of doing good rests in our being so fortunate as to hit on something which happens to make a favourable impression on the disease. I have in the first place prescribed the sulphate of iron in doses of half a grain, combined with one-sixth of a grain of opium, to be taken every third hour. In this way the patient will take from four to six grains of the sulphate of iron in the course of twenty-four hours. I need not explain to you that this remedy possesses powerful astringent effects; as a means of checking hæmorrhage from the stomach and small intestines it has been recommended on very high authority. We have combined with it a small quantity of opium on the same principle which guided us in combining laudanum with acetate of lead in the case of intestinal hæmorrhage to which I have already alluded. If this fails, I have ordered the spirit of turpentine in doses of ten drops *in a spoonful of ice-cold water*, to be taken every half hour. The *rationale* of this prescription is easily understood. Cold acts as an astringent, and tends to excite contraction in the vessels of a part affected with passive hæmorrhage. Turpentine is also well known for its effect in checking hæmorrhage, particularly from small superficial wounds, where the capillaries are principally engaged in pouring out blood. Should these measures prove unsuccessful, we shall have recourse to acetate of lead and opium. I beg leave to observe here, that it is not my intention to give up any of these remedies hastily, and before a sufficient trial has been made; each is to be carried as far as shall be deemed necessary to obtain its specific effects, and the whole process is to be conducted under the superintendance of Mr. Nalty, in whose judgment and discretion I have good reason to confide. If the hæmorrhage should still continue, I have determined to make trial of ipecacuanha, a remedy which has been employed with remarkably good effect by Richter of Gottingen, and by Dr. Sheridan of this city, who in cases of hematemesis was in the habit of giving it to the amount of twenty-five or thirty grains in the day. I have myself prescribed it in doses of half a grain, a grain, and even two grains, every second hour, in pulmonary hæmorrhage, and certainly with very good effects. I cannot explain the rationale of prescribing for vomiting of blood a remedy which is generally followed by vomiting. The patient generally vomits after taking two or three doses, but it is a curious fact that the matter ejected from the stomach contains little or no blood. I shall say no more with respect to this case at present; until the disease has become more developed, or the effect of remedial means becomes apparent, it would be premature to make any further observations.

A few words with respect to the case of Mary Eyre, who has been under treatment for the last two or three days. This woman who is a butcher's wife of sanguineous temperament and highly plethoric habit, her person exhibiting a ponderosity and bulk quite at variance with the idea of spare diet, and her face blushing with gutta rosacea not the result of an exclusive preference for water drinking, has been labouring for some time under rheumatic arthritis produced by cold. Notwithstanding her plethora however, she appears to be a person of excessively acute feelings, her sympathies are reflected on herself with a wonderful intensity, and knowing the value of flesh and blood, she entertains a rooted aversion to every form of sanguineous depletion. She cried bitterly when a few leeches were ordered to be applied to the inflamed joints, and deplored her melancholy fate in terms of the deepest sorrow. It is rather rare to meet with a case of such acute sensitiveness among hospital patients in this country; in private practice you will occasionally meet with such persons, and when you do, you must always make up your mind to bear with a great deal of annoyance.

The history of this case is briefly, that the patient about a week before admission, was exposed to cold, which was followed by shivering, feverishness, rheumatic arthritis, and an affection of the bronchial mucous membrane. By the use of leeches to the joints, and smart purgative enemata, we have considerably ameliorated her condition; her fever is reduced, the pulse has come down, and the cough is not so violent nor harassing. The arthritic symptoms however continue, and with the view of getting rid of these, I intend to put her immediately on the use of colchicum. There is one circumstance however, to which I would particularly direct your attention in this case, and that is the bronchial affection. The patient complains of great oppression about the chest, and severe harassing cough. Now, when bronchitis attacks a person labouring under the rheumatic diathesis, it assumes a peculiar nature, and requires a treatment differing in its principles from that which is employed in simple acute bronchitis. It is not here nothing more than mere bronchitis from cold; it is bronchitis occurring in a rheumatic habit, and modified by the rheumatic diathesis. With regard to treatment, there is also a vast difference between common and rheumatic bronchitis. In the former, you must leech, cup, and blister, and when the acute stage of the disease is past, you must have recourse to various kinds of expectorants; but in the latter, the physician must, after the proper application of antiphlogistic measures, choose his expectorating and diaphoretic remedies from the list of those which experience approves of in the second stage of gouty and rheumatic arthritis.

If the colchicum, which we are about to prescribe in this case, cures the rheumatism, it will cure the bronchitis also. Both of these affections are connected with the same constitutional tendency, and both are amenable to the same therapeutic agents. In gouty and rheumatic bronchitis the action of colchicum is most efficiently aided by some blue pill, and by calcined magnesia; and where the fever and activity of the inflammation are diminished, diaphoretics, particularly Dover's powder, proves eminently beneficial, much more so than in catarrhal bronchitis. The fact that gout or rheumatism has been excited by the same cold which gave rise to the bronchitis, will assist you much in determining the nature of the latter, and there will be no difficulty in the case, if the person has had frequent attacks of gout, and if his pectoral affection immediately preceded or followed that of the joints, *without any obvious cause* such as cold: on this point most writers on diseases of the chest have displayed a remarkable deficiency. No author has as yet given a clear and comprehensive view of the manner in which pulmonary disease is connected with constitutional diathesis. I have alluded before to some important errors committed by Willan and others in the arrangement of cutaneous affections; they have merely attended to the peculiarities of a disease as affecting only one or two tissues, and have almost entirely lost sight of their connection with constitutional diathesis. Hence it is that their arrangements have been so justly found fault with by Alibert, Richter the younger, and many other Continental pathologists. It is the same thing with respect to the diseases of the lung; scarcely any notice has been taken of their connection with certain states of the system, and the only constitutional disease whose effects on the pulmonary system have been at all well studied, is scrofula. The effects of rheumatism, gout, scurvy, and syphilis have been almost completely overlooked.

Before I conclude, allow me, gentlemen, to make a few observations on the treatment of iritis; you are all aware from what you have seen of my practice that it consists in the antiphlogistic treatment, general and local, combined with a prompt exhibition of mercury, the use of belladonna ointment, &c. Now there is one point of practice, not laid down in books, but which is very important, I mean the exhibition of spirit of turpentine internally. This remedy was first recommended in iritis, as is well known, by Mr. Carmichael, junior, of this city; since the date of his last publication on this subject, I have had opportunities of observing its effects, and I have arrived at some conclusions on the subject, by no means uninteresting, for they tend to establish that spirit of turpentine is an excellent adjuvant to mercury in the cure of iritis. Who has not remarked the curious fact that when iritis is yielding rapidly to mercury at the time salivation comes on, the improvement in the eye may cease after a few days in some cases, although the mouth is still sore? The practitioner is then embarrassed, and hesitates to decide whether he shall resume the exhibition of mercury; as he has no other resource, he does so, and again gives calomel freely, and again the eye improves. In a few days the mercury is again laid aside, either because the patient is suffering much from its effects, or because the physician thinks the inflammation is quite subdued; how much is he mortified then to find that in the course of a few days, and without any apparent cause, the eye is threatened with a relapse. The sight again becomes dim and clouded, the zone round the cornea becomes again red, and pain is again complained of. What is now to be done? Is there no other resource but mercury? Yes, gentlemen, I have much pleasure in being able to assert with confidence, that spirit of turpentine is a most valuable remedy under these circumstances; no one, indeed, can justly estimate its value, who has not been placed in the embarassing situation above described. I first tried it in a case that I attended along with Mr. Carmichael, sen. and Mr. Colles. A gentleman, of robust frame, aged twenty-two, had contracted chancres. He remained in the country for several weeks, and then came to town for advice, and placed himself under my care. I directed rest, cooling aperients, and cleanliness for a few days, in order that I might have time to form an opinion as to the necessity of giving mercury. In the meantime, he felt himself not quite well, and one of his eyes became red and watery. I at once feared syphilitic ophthalmia. This new affection resisted the ordinary antiphlogistic means, and in a short time its nature was evident. I had now the benefit of Mr. Carmichael and of Mr. Colles' advice, and mercury was boldly given. In a very short time the mouth was touched, and the iritis checked in its progress.

As our patient had more than once been attacked with a spitting of blood since puberty, we were anxious to cure his iritis with as little mercury as possible, and we, therefore, desisted from its use, as soon as an evident improvement had taken place in the eye. In a few days, however, we were again forced to resume it in larger and repeated doses, for the redness of the eye, the pain in the eyebrow and the dimness of sight had suddenly came back. This time we persevered in the use of mercury much longer, until, in fact, all danger of a relapse seemed over, so much so that both Mr. Carmichael and Mr. Colles took their leave, a step in the propriety of which I fully concurred. Judge, then, Gentlemen, how much I was mortified at observing another relapse of the iritis in the course of a few days, and that while the mouth was still sore, very sore from the mercury previously given. I was much embarrassed as to the mode of practice I should adopt, and felt very unwilling to begin with mercury a third time, fearing that a scrophulous diathesis might be thus acted on unfavourably, and spitting of blood excited at no distant period. At length turpentine suggested itself to my mind; I remembered what Mr. Carmichael, jun, had written on its exhibition in certain forms of iritis, and it struck me forcibly that I was justified by analogy in expecting advantage from its employment; I accordingly gave my patient thirty minims of spirit of turpentine well diluted with barley water three times a day; the effect was most satisfactory; the very next day the eye was evidently better, and it improved steadily afterwards until it became perfectly healthy. We continued the use of the turpentine about a fortnight. Since the occurrence of this case I have met with several others, one of which was under the observation of my class at the Meath Hospital, and for the subjoined notes of which I am indebted to Mr. Mahood:—

Martin Keyburn, ætat. 17, was admitted on 30th May. States that he had an impure connection about two months ago, and that a fortnight after he observed a sore on the penis, or rather, as he describes it, an excoriation, situated at the frænum, to which he applied bluestone, and on the

following day the prepuce became so swollen that retraction was impracticable for nearly six weeks, accompanied with a copious discharge: about this period he with some difficulty effected this object, but the pain and swelling which ensued caused him instantly to replace it, and at the time he observed that the force required caused blood to issue from the abraded surface. The swelling having decreased, he was enabled to retract the prepuce, without much difficulty after a lapse of six or seven days, notwithstanding not having been under the influence of medicine, and on his admission into the hospital he presented the following appearances.

The body densely covered with a syphilitic eruption, pains in the lower extremities, no swelling of penis, but on and about the frænum there is an extensive excoriation, but no hardness; iritis of right eye, left one quite well; no fever; bowels regular.

To commence by a small bleeding.

30th.—Venæsectio ad ℥xij.

℞ Calomel. gr. ij. Ft. Pilula, quater vices in die sumend.

31st.—Rept. Pilulæ. Lotio nigra peni.

June 1st.—The eruption is disappearing, but both eyes are now affected. States he can see very well with left one, but that there appears to be a cloud between him and the object when looking with the right; violent pains in the small of the back; intolerance of light.

℞ Ext. belladonnæ superciliis.
Hirudines xviij. infra orbit.
Enema cath. statim. Rep. Vesp.

2nd.—Eyes better, not so red. Rep. Pilulæ.

3rd.—Rep. Pilulæ.

4th.—Eyes much improved; redness disappearing. Rep. Pilulæ.

5th.—Rep. Pilulæ.

6th.—Omitt. medicamenta; redness disappeared.

8th.—Redness reappeared; bowels regular; sleeps well. Rept. Pilulæ. Rept. Ext. bellad. superciliis.

9th.—Did not get belladonna applied; eyes better; no redness; sore on penis quite healed.

10th.—Omitt. Pilulæ.

11th.—No redness of eyes.

12th.—Eyes have become red, without any attributable cause; other symptoms of iritis show a tendency to return.

℞ Ol. terebinth ℈j. quater vices in die sumend.

13th.—Redness much diminished. Rep. Ol. terebinth.

14th.—Redness disappeared. Rep. Ol. terebinth.

15.—Sleeps well; has nothing to complain of; no venereal eruption. Rep. Ol. terebinth.

This boy continued his medicine for another week, and perfectly recovered. The effect of the turpentine was here very striking and satisfactory. To conclude, Gentlemen, you perceive that though I cannot boast of being the discoverer of the use of turpentine in iritis, I may claim the merit of being the first to employ it to overcome the tendency to relapse where mercury has been given.

PATHOLOGY OF EXPECTORATION.

By S. Wright, M.D., Edin., F.S.A.
Physician to the Birmingham General Dispensary, formerly Senior President of the Royal Medical and Royal Physical Societies of Edinburgh, &c, &c.

When the inflammation is confined to any specific portion of the lungs, say to its diaphragmatic surface, or to its root, or is circumscribed in the interior tissue of the organs, diagnosis by auscultation or percussion is exceedingly difficult, and often impossible; and we know that even in severer cases the signs furnished by the pulse, by the patient's aspect, and by his manner of breathing, are liable to much fallacy, and are therefore little trustworthy in pneumonic attacks such as we have been describing. In these, as in other instances, the indications of the sputa are of the greatest practical value. The following case is recorded by Andral:—"A man, twenty-seven years of age, walked from Guéret to Paris in six days; he coughed a little when he left Guéret, and the wind was very rough. When he arrived in the evening (16th) he felt ill, and shivered, as he had done during the greater part of the journey, and as he continued to do through the nights of the 16th and 17th. On the following morning the shivering left him. On the 18th he felt an acute pain on the right side below the breast, which was a little relieved by hot applications. Fever prevailed on this and the next day, and he continued to cough without expectorating. On the 20th he entered La Charité. Face calm, displaying a yellowish tint about the nose and eyes, sensitive and intellectual faculties unimpaired; strength little affected, lying on his back; respiration free and very slightly accelerated. Deep inspirations could not be made from the pain which existed on the right side. *The sound was perfect on both sides:* cough frequent; sputa yellow, viscid, united into a trembling and transparent, rather abundant mass; pulse frequent and small; tongue humid and clear; thirst; anorexia; belly soft; constipation. The symptoms altogether appeared to indicate the existence of simple pleurisy, complicated with catarrh, but the sputa appeared to M. Lerminier sufficiently characteristic to point out pleuro-pneumonia, notwithstanding the clear sound of the chest. Twelve leeches to the right side. 22nd. The yellowness of the face was more pronounced, and extended over the body; pulse very frequent; respiration rather difficult; cough frequent; expectoration aqueous and brownish, like to the juice of prunes. 23rd. Features of the face altered and collapsed; extreme weakness; inspirations short and frequent. The sound of respiration is perfect all over the chest; it is sonorous everywhere on percussion. Pulse frequent; skin hot; tongue humid and white; nausea continual; constipation. Some hours afterwards the patient vomited a black matter. His features sunk rapidly; he lay on the right side; face pale; eyes fixed; mouth open. *Rale des mourans;* pulse thready. Death in five hours. *Ouverture* forty hours subsequently. The lungs were crepitant on their surface, and engorged with a colourless frothy serosity. On approaching the right lung, we found its tissue reduced to a greyish yellow pulp, crushing under the finger, and infiltrated with a purulent sanies. Grey hepatization was announced by the expectoration on the seventh day. In tracing towards the summit of the lung, we found under its internal faces spots of red hepatization. Gastric mucous membrane was red."

Pneumonia occurring in subjects affected with heart disease, is liable to have the chief of its symptoms masked or made unintelligible by the chronic ailment or its consequences. But it is not possible for us to be deceived in the evidences of the expectoration. Some weeks ago I was hastily summoned to a patient (a man ætat 43,) whom I had previously attended for an attack of acute pericarditis complicated with rheumatism. He had for years laboured under hypertrophy of the right side of the heart, with patency of the tricuspid valves. He was habitually œdematous, his pulse was constantly and irregularly intermittent, he had a frequent cough, easily exasperated, with occasional violent attacks of palpitation of the heart, and painful suffocating dyspnœa. On inquiry, I found that he had been exposed to some inclemency a few days before, and had since that time suffered from an aggravation of his old symptoms. In addition to these, he complained of a dull pain on each side of the lower portion of his chest, slightly increased by forced inspiration. But it ought to be observed that his dyspeptic and rheumatic visitations, which were very frequent, were always accompanied by these thoracic pains. Tongue pale, flabby, and trembling; pulse quick and irregular; thirst urgent; constant cough, and difficult expectoration of viscid opaque mucus. This kind of sputum he was in the regular habit of discharging. The signs of auscultation and percussion were rendered useless by the extremely œdematous state of the parietes of the chest. In the absence of satisfactory evidence to the contrary, I regarded his present condition as an augmentation, *not specific*, of the symptoms of his old disease. He was ordered a mixture of camphor water, ether, hyoscyamus, and laudanum, every two hours, with sinapisms to his feet, and hot fomentations to his chest. In the evening I visited him again, and found him in no respect improved. His sputa, however, had become more transparent and viscid, and were of a bright orange colour. These told faithfully the tale of the patient's sufferings. Contrary to my first impression, I decided that the case was pneumonia, and treated it accordingly with such febrifuges, antimonials, mercurials, and depletives, as my patient's strength enabled him to bear. Under this plan he improved, and at the end of a fortnight was only the chronic sufferer he had been before.

Andral has remarked that in cases of aneurism of the heart, it is difficult to recognise an accession of pneumonia. "Suppose for example" (he says) —and this supposition is too often realized—that an individual already the subject of organic disease of the heart, is suddenly attacked with pneumonia: the unusual increase of respiration, the increase of dyspnœa, the quickened pulse, the more uneasy state altogether which the patient may exhibit, may very naturally be attributed to a sudden increase of the symptoms of the heart affection: and these are what are observed daily. The appearance of cough is not likely to inform us more, for pulmonary catarrh is an ordinary complication of aneurism of the heart; in fine, percussion only gives very imperfect information, in cases where the thoracic parietes are œdematous. The signs furnished by the examination of the sputa, and by the method of auscultation, are alone those which are able to tell us that pulmonary inflammation is present. But auscultation itself, seems to us, insufficient to distinguish a pleuritic effusion from hepatization of the lung. A sailor twenty-eight years of age, of strong constitution came into the hospital St. Louis, and presented the following symptoms of disease of the heart. Dyspnœa, augmented by the least movement, face livid, lips blue, ascitic; œdema considerable in the lower extremities, and in the thoracic parietes; palpitation of the heart, often much increased; pulse hard, regular, and habitually frequent; cough frequent and painful, sputa thick and green. On the 13th day of his entrance his respiration was much accelerated, the pulse more frequent than on the preceding days, the palpitation of the heart stronger, and th face more bloated. Percussion could give very little information on account of the infiltration of the integuments of the chest. (Auscultation was not practised, because it was scarcely known—1819.) This state was regarded as dependent upon disease of the heart. But the next day, the expectoration, suppressed during the night, reappeared with new characters. The patient expectorated a great quantity of sputa, formed of gelatinous transparent masses, of a saffron yellow, detaching themselves easily from the vessel. From the nature of the sputa, M. Lerminier did not hesitate to announce the existence of pneumonia. The sputa went to the height, and then indicated resolution, which followed." (1)

Thick mucous sputum, of variable opacity and density, is discharged in most chronic affections of the respiratory organs. In dilatation of the bronchi, in angina pectoris, in heart disease, in asthma, in subacute bronchitis, especially the lingering form (2) of it which is met with in old people, in every stage of phthisis, but chiefly the second, and in the morning expectoration which attends some varieties of dyspepsia and bilious disorder, it is especially prevalent. With some people it is a permanent trouble, capable of being aggravated or relieved by

(1) Op. cit. p. 46.

(2) In some cases, this kind of expectoration alone prevails throughout the whole course of phthisis. It was first observed by Dr. Huxham in his Observations de Ære et Morbis Epidemicis Plymuthi factæ; 1752. Dr. Gilchrist next alluded to it in his work "On the Use of Sea Voyages in Medicine; 1756. It is now well enough known that phthisis may terminate fatally before the tubercles are softened, or even passed from their primitive state, and it is not common in such cases for the sputa to be purulent; but Andral says that he has seen examples of phthisis, with the softening of tubercles and the formation of caverns, and yet the expectoration was mucous throughout the disease. *Clin. Med.* trans. by Spillan, p. 474.

atmospheric and constitutional variations, but never entirely subsiding (3). In certain seasons, also, as the spring and autumn, it commonly undergoes a marked increase. A sudden cessation of the cough and expectoration, particularly in old people who have been for years the subject of them, is often succeeded by apoplexy, paralysis, or sudden death.(4.) Its most gradual decline in adult life is apt to be followed by gout, gravel, cerebral disturbance, or gastro-intestinal disorder; and in advanced life, by local or general dropsy, visceral diseases, congestions, &c. An arrest of the more viscid and transparent form of this sputum is instantly followed by an aggravation of the pneumonic symptoms, and not rarely by fatal hemorrhage from the lungs. A resolution of the disease which this sputum accompanies, is indicated by the latter passing into the more opaque and diffluent form of its own variety, or into the "thin insipid mucous sputum." The progress of the disease, on the contrary, is marked by the expectoration becoming "purulent" and ash coloured, or fœtid," or thin, tinged with a colour like that of prune-juice.

(3) In many of these cases the discharge appears to be a kind of peculiar catarrhal affection, just as with some subjects a similar sort of defluxion occurs from the nose. It is often, also, excessively offensive. Frank, in treating of catarrh, says "tandem nunc citius, nunc tardius, loco seri pellucidi, liquidum paulo crassius, mucosum, ac sensim, sensimque, cum facilitate majori, glutinosa, vel alba, vel flava, interdum subviridis, vel striis ex sanguine remistis, *sat fœtidi subinde, odoris*, pituita, copiose ac plures per dies emungitur." De Cur. Hom. Morb. Epit. 5. 108. Andral has met with cases of simple bronchitis in which the odour of the sputa was nearly equal to that of the greyish sputa of gangrene of the lungs. As no particular lesion of the bronchi existed that could account for it, it was naturally enough referred to a peculiar alteration of the proper bronchial secretion. *Clin. Medic.* trans. by Spillan. 304-5.

(4.) Sometimes it happens that the cough and expectoration of chronic bronchitis will cease, though the secretion from the bronchial membrane continues, and this fluid pouring into the minute bronchi and air cells, fills them and occasions death by asphyxia. Andral relates a remarkable case. A man, forty-five years old, having had the preceding year a pleuro-pneumonia, entered La Charité in August 1820. Since his illness he had continued to cough; he complained of his respiration being habitually embarassed; all the right side of the chest, when percussed, yielded a very dull sound. The patient lay constantly on that side; breathing short, cough frequent, with expectoration of a great quantity of opaque mucus, resembling the sputa of chronic bronchitis; pulse hard, but not frequent. Great emaciation, functions of digestive organs intact. Same state during the fifteen days following. All at once, on the night of the 15th Sept., the patient awoke in a state of imminent suffocation, and expectorated in a very short time an enormous quantity of mucous sputa, which he seemed really to vomit. They united into a homogeneous mass of a greenish yellow colour, which flowed from the vessel when inclined. However, this liquid being continually carried into the trachœa and larynx, and filling them more rapidly than it could be expectorated, soon suffocated the patient.

In this case, the excessive secretion which took place suddenly on the inner surface of the air tubes, had been preceded by chronic bronchitis; it was only the expectoration usual in this disease, which, without any known cause, without any appreciable exasperation of the inflammation, became so abundant, and so rapid all at once, that the patient died asphyxiated, as in the case where a purulent or sanguineous tumour opens into the bronchi."—(Clinique Medicale, trans. by Spillan, p. 310.)

The unfermented bread of Mr. Dodson for the use of invalids, has been submitted to our examination by its ingenious inventor. We are happy to be able to say that the encomiums of so many of our learned brethren in its favour are not undeserved.

PROGRESS OF FRENCH SCIENCE.

FROM OUR OWN CORRESPONDENT.

Paris, May 29, 1845.

On a Species of Paralysis peculiar to Nurses.—M., ætat. 25, was confined ten months ago, and suckled her child, which was affected with *syphilides*; she has been ailing for the last four months, though not sufficiently so to be laid up; about a fortnight ago, after a violent attack of diarrhœa, she was affected with a peculiar rigidity in the muscles of the arms and legs, and especially in those which move the fingers, which were incapable of voluntary motion, though they could be bent, and extended without causing pain; the muscular contraction was not continuous, but for a few minutes only, with an interval of several hours; as soon as the spasmodic contraction was past, the parts assumed their normal condition; fever, and red tongue. All these symptoms soon yielded to venesection. Professor Trousseau remarked, that he had had frequent opportunities of seeing perfectly analogous cases, and they were rapidly cured by the same method of treatment.

On Accidental Retraction of the Limbs; by Morel Lavallée, D.M.P., former *interne* to the Paris Hospitals, and laureat of the same, Member of the Anatomical Society, &c.—(continued).—*Diagnosis:* The signs of retraction (when caused by a cicatrix) are so evident to sight and touch, that the lesion can be readily recognised. Its characters will be given in a few words at the end of this chapter, which will be almost entirely devoted to the examination of retraction of the muscles and normal fibrous tissues, it being principally these two varieties which may be confounded either with each other, or with lesions of the osseous system. Some of the forms of all these are so clearly distinguishable that we may pass their diagnosis by. Such are those which have not their origin in an articulation, but are either caused by a disturbance of the nervous system, or by direct lesion of the muscles, the cellular tissue, or the aponeuroses, by pressure, wounds, &c., with anchylosis, produced by the formation of an osseous tumour, which, extending from one bone to the other, prevents motion. The only case which might perhaps present some difficulty is, when after a chronic affection, the articulation has become less mobile; this may be owing to osseous vegetations formed around the joint, or the retraction of the muscular or fibrous tissues, especially after rheumatism, which is as frequently followed by the one lesion as the other. But each has its characteristic signs, which are easily appreciable when the seat of the disorder is superficial; the former by the abnormal osseous swellings around the articulation, the latter by the tension of the retracted tissues. On the other hand, when these exostoses, muscles, aponeuroses, and ligaments are so deeply situated as not to be felt, how is the diagnosis to be established? The following sign was of service in a doubtful case, in which the diseased part (now in the author's possession) was examined after death. When we endeavour suddenly to place the limb in its natural position, we find ourselves stopped all at once by a shock which is too sharp to have been produced by the soft parts, which are but moderately on the stretch. Another sign of incomplete osseous anchylosis is, that the morbid condition which has deformed the articular surface or its edges, very seldom limits the mobility in one direction alone, as motion is almost always diminished in the direction in which the limb is bent. These two signs—the shock and the limited mobility—existed in the case above-mentioned, in which, after an attack of arthritis, the right elbow remained in a state of permanent semi-flexion, and whenever an attempt was made to bend or extend the limb, the surgeon was stopped suddenly by the sharp shock already mentioned. The patient died of phthisis in the wards of Professor Dumeril, and at the *post mortem* examination a bony excrescence was discovered, which encroached on the surfaces of the articulation, and considerably diminished their extent, both anteriorly and posteriorly. In muscular and fibrous retractions, the parts resist when the operator seeks to straighten the limb, but the resistance does not take place suddenly, and is not accompanied by a shock, but by the tension of the affected parts—a tension which is visible when they are sub-cutaneous. Moreover, it is possible, except when the limb is retracted to its utmost limits, as the fingers in the palm of the hand, the foot against the anterior surface of the tibia, &c., to render the retraction greater,—for instance, when the leg is in a state of semi-flexion, it may be bent so as to touch the thigh, the contrary motion alone (extension) being impracticable. In the hand and foot, the possibility of moving the articulation just above the one affected, and in a direction opposite to the retraction, furnishes an important diagnostic sign. Thus, if the second phalanx is permanently flexed, while the first is easily extended on the corresponding metacarpal bone, the palmar aponeurosis, and the flexor tendons are not engaged in the disease, the causes of which must be sought for in the bands described by Dr. Goyraud, as extending from one phalanx to the other—in the shortening of the lateral ligaments, which are favorably situated to produce such a result, or in lesions of the bones. The bands in general do not exist without a shortening of the palmar aponeurosis, and the sharp noise or shock already described, if it be possible to hear it in such small bones, indicates a lesion of the osseous system, whereas, when these two are wanting, it is highly probable that the cause consists in shortening of the ligaments.

When incomplete anchylosis and retraction exist at the same time, the signs of the two are mixed, and generally each is rendered more difficult of diagnosis; the peripheral osseous vegetations are perhaps the only ones which may almost always be readily felt. The diminution of the movements produced by the lesion of the bones renders it impossible to appreciate, by extending the limb, the degree and even sometimes the existence of the retraction, and this last, by limiting the motion, tends to render the osseous shock less sensible or entirely imperceptible. This, however, may sometimes be observed by relaxing the retracted tissue as much as possible, by the position of a neighbouring articulation; for instance, the muscles of the ham, by extension of the thigh, &c. With respect to the treatment, it is highly important to ascertain whether the retraction is complicated with any considerable lesion of the articulation; this may be ascertained by properly appreciating the value of the more or less marked, and more or less numerous signs, which are found in combination. The differential diagnosis of muscular and fibrous retractions is worthy the greatest attention, because on it often depends the choice of the method of treatment. In establishing this comparison, those cases which, having lasted some time, present a certain degree of severity, and consequently are of practical importance, will be taken into account. Thus, we shall not examine the instinctive spasmodic contraction of the muscles, which takes place in order to prevent a painful movement, or a change of position in a fracture, of which spasm a curious example has been published by the author. Is it not superfluous to occupy our time with subjects so simple and so clear?

There is a muscular retraction which cannot be confounded with any other; it is symptomatic of disease of the encephalon. It may, if sufficient attention be not paid, escape observation at its commencement, and even at a more advanced stage, if it affects children: thus a convulsive affection may appear, and seem to have terminated favourably, whereas, in reality, it has left behind it a club-foot, which the carelessness of the nurse prevents her perceiving until six months afterwards, when the child's foot is put to the ground. This neglect, which the author has once witnessed, fortunately does not often occur. The retraction, produced by a morbid over-excitement of the nerves, is limited so precisely to the parts in which these last ramify, that this circumstance, added to the previous lesion of the nerve itself, at once removes all difficulty. The same remarks are applicable to that caused by paralysis, or the section of antagonising muscles. The retractions of the aponeuroses, or bridles, which are seen or felt under the skin, in a direction or distribution different from that of the muscles of the part, will like the long falciform band observed by Professor Gerdy on the inside of the arm, constantly

on phlegmonous erysipelas, be easily recognised by this sign.

The only parts of these two systems—and they are numerous—in which these retractions may be confounded, are those similarly disposed; for instance, the muscles and their sheaths, and the aponeuroses, and flexors of the fingers and toes. In these cases, the tension, shape of the affected organ, and the pain produced by traction, are the same; besides which, their causes, mostly of rheumatic origin, favour both hypotheses. How, then, can the difficulty be solved? In the first place, muscular and fibrous tissues present a marked difference when the lesion is carried to a certain extent, in the mode in which they yield to the efforts made to extend the limb; for the former will permit its being straightened to an extent which the latter could not allow without rupture. Thus, a permanent semi-flexion of the leg may be made to disappear almost entirely when it is owing to muscular contraction, without causing much pain or any serious disturbance; and if there are some cases in which this sign is scarcely evident, its importance is diminished, but it is not valueless. In a similar case of flexion, when produced by a fibrous retraction, the extension cannot be obtained without rupture, as is evident from the crackling noise which is heard. Secondly, when the operator seeks to place the limb in its normal direction, the part which is the cause of the flexion, is more or less stretched. Now, if the fleshy part of the muscle, parallel with the aponeurotic bands, remain soft, it evidently has nothing to do with the affection. On the contrary, if it become hard, though this may lead to the supposition that it is the cause of the affection, still it does not positively indicate it, because the pain produced in the fibrous tissue by the traction, may induce contraction in muscles which are in their normal condition. In order to avoid this insidious co-operation, and to obtain useful indications from the physiological consistency of the nerves, the part must be examined with the utmost care, and extended slowly and gently. This condition of the muscles of the forearm is especially useful in the differential diagnosis of retractions of the fingers, and even in cases in which it would appear to be impossible; viz., when the lesion is produced by the aponeurosis which covers the centre of the muscle, which, owing to this, may by its contractions be supposed to be the cause. In these cases, the antibrachial aponeurosis by its union with the palmar, may produce flexion of the fingers or wrist. The relation of the following case, taken from a memoir by Professor Gerdy, will indicate the signs by which muscular may be distinguished from fibrous retractions; the remarks of the learned Professor will explain the theory of these lesions.

Case.—Dubreuil (Jean) ætat. thirty-four, joiner, entered la Charité on the 26th February, 1844, having at the union of the upper and middle thirds of the forearm a longitudinal wound about four inches in length, made by a plane. At the moment it occurred he went to another hospital, where the lips of the wound were united by strips of sticking-plaster around the limb; which having been followed by erysipelas between the wound and the elbow, were removed by the patient himself before he came to la Charité. 27th. Edges of the wound separated, swollen, allowing the tendon of the radialis internus to be seen; movements difficult, on account of the erysipelatous tumefaction of the upper part of the fore-arm. From 28th February, to 16th March, the erysipelas yielded to lotions with Goulard water; the wound which had been dressed with linen, simple cerate and lint, was partly healed. 17th March, the inferior two-thirds alone completely cicatrized, the superior third covered by granulations; he had difficulty in extending the hand and fingers, which increased daily. 23rd. Wound nearly cicatrized, fore-arm bent on the arm; the hand forming a slight angle with the fore-arm; fingers more than half bent; the third phalanx alone could be extended. In examining the fore-arm, whilst an assistant endeavoured to straighten the fingers, a marked retraction produced by powerful tension of the antibrachial aponeurosis, was felt immediately under the skin, extending from the bend of the arm to the palm of the hand; superiorly this retraction reached from the epitrochlea to the centre of the bend of the arm, descended obliquely to the palm of the hand, passing under the wound, and was of a triangular shape, the base being situated superiorly; when the hand was extended, it jutted out sufficiently to be very visible; under the upper half of the wound a considerable induration could be felt, about an inch in breadth and two in length, adherent to the wound, and also to the fibrous layer just mentioned; it followed all their movements and could not glide over the aponeurosis like the lower part of the cicatrix, and the skin of the rest of the limb. Emollient poultices, tepid arm baths.—31st. The remedies employed having produced a slight improvement, the hand and fingers were submitted to gradual and forced extension, during which a noise was heard as if something had snapped, accompanied by a smart twitch of short duration, after which the parts yielded, and the result was that the fingers and hand could be almost completely extended; a part of the retracted tissue had evidently been ruptured, not elongated, since the adhesion, the induration, and the retraction of the aponeurosis caused by the lesion of its tissue still existed. Emollient poultices and arm baths were prescribed, and a splint extending from the bend of the arm to the tips of the fingers applied.—3rd April. Extension was made a second time, and caused another rupture; fingers and hand could not be entirely extended; a tense band passing under the cicatrix (the upper two-thirds of which adhered to it) still extended from the bend of the arm to the wrist; its breadth superiorly was about 2½ inches; opposite to the cicatrix, three-quarters of an inch; and from this part to the wrist about an inch; its length from the bend of the arm to the induration about two inches.—16th. For the last week the splint had been removed, and the poultices no longer applied. The changes remarked were—the fore-arm, hand, and fingers could be completely extended; induration under the wound not diminished; no tension nor retraction between the cicatrix and the wrist; but from the cicatrix to the bend of the arm it still existed; but the breadth of the aponeurotic band which produced it was not so visible, its edges being united to the surrounding tissues; cicatrix adhered only to the aponeurosis and not to the tendons, which move freely under it.

It may be concluded from the preceding, 1°, that the cause of the retraction originated in the wound; but as it was complicated with inflammation and suppuration, and followed by cicatrization, there remains to be considered to which of these circumstances the retraction ought to be attributed. This however can only be decided by comparing this case with analogous ones whenever they occur. 2° That the lesions consecutive to the wound and its cicatrization consisted (*a*) of an induration of part of the cicatrix, and its close adhesion to the subjacent cellular tissue and layers of the antibrachial aponeurosis; (*b*) of a retraction of the antibrachial aponeurosis, principally above the cicatrix; (*c*) of an increased breadth of the bridle, as it was examined higher up.—3° That it is far from being proved, nor indeed is it probable, that a muscle participated in the retraction of the hand and fingers, which occurred during the cicatrization of the wound. In fact, in the first place, the muscles were soft, supple, flexible, not painful, and contractile as in their normal condition; secondly, the retraction of the aponeurosis, which evidently existed, was sufficient to account for the flexion of the hand and fingers. As to the noise heard when the part was forcibly extended, it may have been produced by the rupture of a recent adhesion between the tendon of the radialis internus, the anti-brachial aponeurosis and the cicatrix (the palmaris longus was wanting); or by the rupture of some of the fasciculi of the retracted aponeurosis. The latter is most probable, for the patient felt the pain only on the inner side of the cicatrix, and not at all in the tendon of the radialis internus.—4° That attentive observation shows that the affection was not dangerous; the forced extension of the hand and fingers was not very painful; the flexion caused by mechanical retraction almost entirely ceased when the parts were extended; and the retraction afterwards gradually diminished by the application of an apparatus, emollient poultices, and baths.*

This patient was examined by the author at a period when the aponeurotic retraction still visibly existed. When the fibrous band does not extend on the fingers, parallel with the tendon of the last retracted phalanx, and when in cautious extension of the parts, the resistance is offered by the third phalanx; it is the flexor digitorum profundus which keeps it bent, at the same time that it acts on the others consecutively. On the contrary, if it be mobile, while the others remain permanently flexed, as the author observed in a patient of Professor Velpeau, the cause is to be sought for in the flexor digitorum sublimis, or in a fibrous band. The mode in which the parts resist when traction is made, the firmness of the muscles of the fore-arm, the state of the skin in the palm of the hand—often shortened and hardened—and finally, the state of the sub-cutaneous bands or the palmar aponeurosis, tend to elucidate the question.

The comparison, with respect to the diagnosis, between deformities of the limbs produced by lesions of the soft parts, or of the bones, by muscular or fibrous retractions, has already been examined; but in order to carry the distinction to its utmost limits, the precise seat of the retraction in the two systems ought to be pointed out, that is to say, the band or the muscles affected. But this precision, which is in general easily attained, is of very little importance, except when the lesion is situated in the flexor muscles of the hand; the means by which they may be recognised have already been detailed.

Before closing this chapter a few remarks may be added on the diagnosis of cicatrices, viz., that it is highly useful to distinguish not the nature of the retracted tissue, this being evident, but to examine, 1°, its thickness; 2° its connexion with the subjacent tissues, with which it may be united; 3°, whether adhesion has taken place with a tendon, in which case it is impossible to obtain and dangerous to attempt the re-establishment of the cavity—the chest in retractions of the arm, or abdonormal motions; with a vessel or any important men in those of the thigh; with an articulation; 4°, its extent, its strength, and the inconveniences it produces in the functions of the limb; finally, it must not be forgotten that three species of retractions, and especially the two first, often complicate one another, and that each must be diagnosticated by its peculiar symptoms.

On the efficacy of Ipecuana in Bilious Dysentery. By A. Millet, of Tours, D.M.P.—Though opinions are unanimous as to the necessity of having recourse, in this affection, to remedies supposed to act promptly and efficaciously, yet they are far from being so with respect to the preference which ought to given to some rather than to others; thus, by turns, antiphlogistics, opiates, tonics, emetics, and many other substances have been recommended. Now these various remedies, which are really useful, when judiciously administered, may become injurious when given at a wrong time. In the present article, the author 1st, enumerates the cases in which certain remedies ought to be preferred; thus in simple inflammatory dysentery, antiphlogistics first, and then opiates: in bilious dysentery, purgatives, if there be constipation; or emetics, if diarrhœa exists: in slight ataxic dysentery, opiates; in adynamic dysentery, tonics. 2nd, Passes in review the various epidemics recorded since Ipecacuana has been employed as a therapeutic agent; in all it acted only as an emetic, and when an emetocathartic was requisite, it was replaced by tartar emetic. It cannot, therefore, be admitted (according to the author,) with Cullen and Professor Trousseau, that the efficacy of this substance is in proportion to the number of stools it produces, more especially as its purgative properties are very slight. 3rd, Gives at length three (of five) cases in which this substance was administered with success. Case I. Miss S., aged 62, good constitution, lymphatico-sanguineous temperament, was attacked in the night of the 31st July, 1844,

* *Gerdy: Retractures des Tissues Albugines. Bulletin de l'Academie de Medicine.* 1844, vol. ix. p. 766.

with a shivering fit, which lasted two hours, followed by pain, especially at the anus, and by frequent stools. 1st August. Brow-ache; features altered; yellow tint around the lips; bitter taste in the mouth; tongue dry, and covered with a thick yellow coating; breath fetid; thirst; anorexia; nausea; abdomen painful; borborygmi; rumbling noise in the left iliac fossa; pulse feeble, 104; urine scanty. ℞ Rad. Ipecac. cont. ʒss.; aquæ puræ, ℥iij. coque per decem minut. cola; deinde adde; syrup simpl. ℥ss.; aquæ distill. flor. aurant. ʒj. M.ft. mist.: cochl. magn., quart. part. hor. sumend. Pro potu, decoct. oryz. sativ. cum. syrup. pyr. cydon. 7, p.m. Prostration; brow-ache less intense; tongue not so foul; thirst less; abdomen no longer painful; skin warm and moist; pulse 108; after each dose of the draught abundant vomiting of bile, of a leek-green colour; no stools, colic, borborygmi nor tenesmus. 2nd August. Passed a good night; tongue clean, moist; no thirst; abdomen supple, not painful; skin cool; pulse 76; some appetite, to take a little rice. The improvement continued, and Miss S. on the 6th was quite well. In the second case, the patient was seventy-six years old, the ipecacuanha was given as follows: ℞ rad. ipecac, ʒj. aquæ puræ, ℥v. coque ut antea, cola, deinde adde syrup. flor. aurant ℥j.—A table-spoonful every ten minutes until half be taken:—cure in eight days. In the third case, the patient was a little girl, eight years of age; the dose of ipecacuana was ʒss in ℥ij of water. Cure in five days. These cases prove that ipecacuana has powerful antidysenteric properties, and acts as an emetic, and not as a purgative. *(Journal des Connaissances Medico-Chirurgicales.)*

On Pressure in the Treatment of Popliteal aneurism. By Dr. Geraldis, *agrégé* at the University, Paris.—Modern surgeons have rejected pressure in the treatment of popliteal aneurism, not only because from the recent progress surgery has made, it is easy to isolate and tie the femoral artery, but because they consider it to be rarely successful, to require a considerable time, and to produce violent pain. Guthrie, after witnessing a case in which White obtained a cure, declares, that no one can hesitate between the ligature and pressure, and that if any one employed the latter once, he would never be tempted to give it a second trial. This method, however, may be useful in many cases, as has been proved by the trials made by Dubois, White, Viricel, Dupuytren, and in 1843 by Hutton, Cusack, and Bellingham in Dublin. Hutton employed it on a man aged thirty-three, who was cured in nineteen days; Cusack on a man aged 55, cured in eight days; Bellingham on a man, aged thirty, cured in sixteen days; pressure was made on the artery in the groin. Mr. Liston in London, in 1843, cured a man after two and half weeks' treatment. Messrs. Allan and Greatrex, two others in 1844; Mr. Liston, a second case in 1844; and, finally, Dr. Bellingham, a man afflicted with femoral aneurism, who had been cured by the same method, of popliteal aneurism on the opposite side. The number quoted by different authors amounts to fifteen; of these Dr. G. analysed eight; in which the average duration of the treatment was twenty-four days; the minimum five days; the maximum ninety days. These results prove that this method is deserving of serious attention, and of being tried before the ligature is had recourse to, because the disease sometimes relapses after the ligature, as Sir A. Cooper, Sir B. Brodie, Professor Roux, and Dr. Lenoir have observed, and because serious consecutive accidents, such as hemorrhage, wounds of the vein, and even death, sometimes take place. In order to avoid the pain attendant on pressure, a pad, shaped like a thumb, made to act, by means of a fine screw, only on the artery, is necessary. This apparatus must be placed so as to make the pad press the artery against the pubes. At first the pressure must be sufficient to prevent the passage of the blood, but must be diminished after a certain time, so as not to fatigue the patient and excoriate the part. By taking these precautions, it may be asserted that popliteal aneurism may be cured as surely and as rapidly by pressure as by the ligature.—*(Journal de Chirurgie.)*

GARLAND DE BEAUMONT, D.M.P., B.L., & S., &c.
Honorary Physician to the Spanish Embassy.

PROGRESS OF GERMAN MEDICAL SCIENCE.

By SIGISMUND SUTRO, M. D.

Fatal Epistaxis, vicarious of the Catamenia.*—Th. A. von M., æt. 19, slight conformation, thin skin, light air, and blooming complexion, at the time of puberty was affected with congestion of the head, palpitation of the heart, shortness of breath, and great debility,—so that she could no longer follow her usual avocations. Instead of the menstrual flux, which never appeared, she suffered from epistaxis, so copious as to cause exhaustion, and the hæmorrhage could be arrested only with great difficulty. Subsequently to this, she improved considerably, and seemed to enjoy perfect health, when the first-mentioned symptoms reappeared, and were followed by another violent attack of epistaxis. Symptoms of inanition were present, and the girl lost flesh, but could not be induced to take any remedy. These bleedings reappeared four times, at intervals of six weeks, when dropsy supervened, and at a later period hemiplegia occurred—the power of speech was lost, deglutition became difficult, and at last she died perfectly exhausted.—*(Dr. Fricker, in Wurtemb. Med. Correspondenzblatt.)*

Conception Occurring during the Existence of Ovarian Dropsy of Twelve Years Duration.—I. A., ætat. forty-one, observed twelve years ago, that towards the right side of the hypogastric region a swelling commenced, which constantly increased in size. But as she felt neither inconvenience nor pain from it, she sought no medical aid, and with the exception of some domestic remedies left the complaint to nature. In her fortieth year she married and became pregnant. On the 20th of March, a. m. she was delivered by the forceps of a still-born child. With the placenta a quantity of ropy, yellow, gelatinous fluid was discharged, which was believed to be the contents of a ruptured cell of the degenerated multilocular ovary. The mother was greatly exhausted by subsequent hæmorrhage, and was in great agony when the author was called in on the 28th; she was then suffering from severe and burning pains in the abdomen. An enormous, unequal tumour filled the cavity as high as the navel; in some places, particularly in the right iliac region, it presented an almost cartilaginous hardness; towards the left it was rather softer, and fluctuation was distinctly perceptible. The uterus presented a painful tumour in the left iliac region, being displaced towards the left by the pressure of the ovary, which was ascertained after death to weigh twenty pounds. The patient died in an hour after the author's visit. *(Dr. Melion in Oesterr. Medic. Wochenschrift.*

Staphylomatoma (from *Staphule* the uvula, so called from its resemblance to a grape and hæmatoma—a blood-tumour).—The author has observed three cases of that disease of the palate, called hæmatoma palati. It consists in the formation of one or several bladders, filled with fluid blood, and covered by the epithelium of the mucous membrane of the palate or uvula. If punctured, fluid blood is discharged. It causes no other inconvenience than a slight pain in swallowing or chewing, according to their situation. If not punctured, the contents are either absorbed or the tumour breaks, leaving a superficial, slightly painful ulcer, which heals in a few days. The causes are not known.† One patient asserts that he has suffered from it once every year. A slight difficulty in eating sometimes preceded its appearance. It is about the size of a hazel-nut, and was always accompanied by aphonia, which was invariably cured by puncturing the tumour. *(Dr. Volz in Heidelb. Medic. Annalen.)*

Case of Œsophagotomy.—N. swallowed a large piece of bone during dinner (19th February, at noon). Notwithstanding repeated venesections, the bone could not be pushed into the stomach. After the injection of clysters of belladonna, attempts were made with levers and forceps, but without success. Injections of tartar emetic and œsophagotomy were both strongly objected to by the patient, who could only obtain relief by occasional injections of oil. On the 23d of February, the pain was so excruciating, that he declared himself ready to submit to any measure that was advised. Tartar emetic was then injected into a vein, at about 8 o'clock A.M.; this excited such powerful vomiting, that clysters of water, vinegar, and at last, of tincture of opium, became necessary. At 4 o'clock P.M., œsophagotomy was performed. The bone being felt from without, above the clavicle, the throat was opened in that situation, and even during the performance of the operation, it was swallowed by the patient (a sign that he might have been saved, if it had been performed earlier). The operation was successfully terminated, a bandage applied, and cold water, with solution of lead, continually applied over the wound. On the 24th, he was very feverish; the next day the extremities became cold. On the 26th, at 2 A.M., there was singultus, and at 6 A.M. the patient's sufferings were terminated by death. The *autopsy* showed that the upper and middle parts of the pharynx were gangrenous, and the opening larger than it had been made by the knife. The lower end of the pharynx, the stomach, and duodenum were inflamed. The bone was already near the rectum. *(Dr. Martini in Wurtember. Medicin. Correspondenzblatt).*

Clonic Spasm of the muscles of the face, and of the orbicularis palpebrarum cured by galvano-puncture—A government employé, aged forty-five, suffered two years ago from acute rheumatism, which ended in rheumatismus vagus, and subsequently a most annoying rheumatism of the left side of the face. The muscles of the left side of the face and of the left eylid, were often rapidly contracted and relaxed, and maintained a wry appearance even when at rest. If the hand was laid on the musc. zygomatic. major and minor, on the levator anguli oris, the orbicularis palpebr. near its tendon, or particularly near the foramen infra-orbitale, the contraction could be distinctly perceived. The left eye appeared smaller than the right, the mucous membrane was pale, and the patient squinted during the paroxysms; the power of vision was more or less affected; the lachrymal secretion not increased, and there was no alteration in the pupil. After employing several remedies without benefit, the author used (subsequent to a remark of the patient's, that steel spectacles had afforded him some relief,) the galvano-acu puncture four times, and effected a complete cure by its means.—*(Dr. Neuhausen of Aldekerk in Rhein. u. Westphal. Correspond. blatt.)*

The Injurious Influence of Newly-Built Houses on the Health and Life of their Occupiers.—First, the author mentions the intimate connection kept up between the external air and the human organization, through the medium of the skin and lungs, then he refers to experience to show the slow and dangerous diseases to which inhabitants of newly-built houses are exposed, and he considers it, therefore, to be the duty of the sanitory police to remove or check these evils, by means of decisive prohibitory measures. The normal composition of the air is changed in newly-built houses, and thus diseases are created:—1st, *by an increased proportion of water* in the atmosphere; (*a*) from the wooden materials, which may be too new and damp, and which, therefore, fill the enclosed spaces with humidity, from evaporation; (*b*) from the stone materials, of which burnt bricks contain and attract the smallest proportion of humidity—field-stones more—sand-stones, and those prepared from dried clay, most; (*c*) from the materials used for cementing the stones, and for coloring and varnishing the walls. The mortar used for cementing the stones, consists of hydrate of lime, which gradually loses its water, and hardens by attracting carbonic acid from the atmosphere. The walls of those houses remain damp longest which have been plastered immediately after their completion, because the dried lime forms an external layer very difficult of

* *Epistaxis* (from a Greek word signifying "to distil from") bleeding of the nose with pain or fulness of the head; females after menstruation are less subject to it than males.

† In a case we have lately had an opportunity of observing, the complaint was distinctly referable to a violent fit of coughing. It yielded to an astringent gargle.—ED. *Med. Times.*

penetration. As accidental causes, which may render houses damp, it is necessary to mention wet weather when building, damp situations, large cellars, and enclosure by other high edifices, which prevent the free access of sun and wind. 2nd, *The proportion of carbonic acid in the air* is diminished by the mortar which attracts it from the air, as before mentioned; it may also be attracted by colours containing acetate of copper, in which case the acetic acid escapes. No direct injury would, however, be caused by the diminution of carbonic acid, as it belongs to the matters excreted by the skin and lungs. 3rd, *The following foreign substances are mixed with the air:*—(*a*) *particles of lime*, which have been proved beyond doubt to exist in the atmosphere of new habitations, being suspended by the evaporation of the moisture; (*b*) *evaporation* of oil and metallic colours. Combinations of lead, copper, and arsenic are employed in the preparation of painter's colours. Lead volatilizes at the increased temperature of the rooms, copper does not, but wherever arsenical colours have been used, the air may absorb arsenious acid, and arseniuretted hydrogen gas may be formed by combination with hydrogen; (*c*) different chemical evaporations of damp new wood, mould, fungi, and grasses, which arise and putrify in damp habitations. P. Frank has already directed attention to the mould with which the furniture of newly-built houses is covered, and to the constant moisture of the clothes and linen, from which circumstance alone influences injurious to the inhabitants may be expected; for on account of the increased humidity of the surrounding atmosphere not only is the skin prevented from free transpiration; but it is even induced to attract more moisture. This is also the case with the lungs, and thus the composition of the blood is rendered abnormal, and hydræmia of the whole body is produced; this is shown by a pale anæmic face, wasted muscles, decrease of strength, sluggishness of all the functions, difficult respiration, and soft small pulse, which symptoms frequently terminate in external or internal dropsy. In other cases, protracted rheumatisms, articular inflammations, contractions or paralyses, are produced. In addition, the sojourn in a damp atmosphere is a frequent cause of the development of scrofula, intermittent and typhoid fevers, scurvy, quinsy, croup, pulmonary gangrene, puerperal fever, &c. Wounds and ulcers easily assume an unhealthy appearance, and have a tendency to take on gangrenous inflammation. The evaporation from organic substances favours the production of miasmata and contagions, for in no situations did the cholera occur more frequently, than in new, damp habitations. The inspiration of lime-particles may predispose to diseases of the chest, or apoplexy. There can be no doubt, that the lead employed in painting the walls, evaporating at a higher temperature, may produce in those who are constantly exposed to its injurious exhalations, symptoms of chronic poisoning, disturbed digestion, colic, or paralysis, but this may be less feared from paints coloured by acetate of copper, inasmuch as it does not volatilize, and could, perhaps, at most, by attracting carbonic acid, allow its acetic acid to escape. Chronic poisoning by arsenic may be produced by being exposed to the evaporation of Schecle's or Schweinfurt's green, from which arseniuretted hydrogen and arsenious acid often escape for a long time. Lastly, the constant moisture of the clothes and beds, and the frequent effect on the food causes certain injurious consequences on the constitutions of the inhabitants. Since then the early occupation of newly built houses and recently plastered rooms causes so many diseases, and imparts to children the germs of prolonged sickness and misery, it becomes the duty of the state to prevent those evils by all possible means. In order to guard against the perils and injuries enumerated, the author considers the following measures to be necessary. 1° Official examination of the materials before the commencement of the building, the enforcement of proper arrangements as regards the building itself. Thus, in public contracts for any building, to be erected in summer, the condition ought to be made, that the materials should be procured and dried during the preceding winter, and the term of completing any edifice should always be regulated according to the weather. Lead and arsenical colours for painting the walls should be entirely forbidden. 2° A house should not be inhabited before a fixed time after its completion had elapsed. Some authors think a year should be the period fixed. Considering the different effects of different localities, a house in town should remain uninhabited for a year, and in the country, where sun and air have free access, for half year after it has been finished. Should any house be dried before the time appointed, the proprietor might request the sanatory commission to examine it, when, if sufficiently dry, it might be inhabited. 3° A commission should be appointed for the purpose of examining every newly built house, and testifying to its soundness before it is inhabited. Austria presents evidence of the feasibility of such an arrangement. 4° Instruction of the people as regards the injuries caused by inhabiting newly built houses, &c., and as regards the means to be taken for the purpose of counteracting these injuries. The above commission not being generally introduced, nor put in force in cases of repairing, painting, &c., people ought to know to what diseases they are liable by exposing themselves to such injurious evaporation, and if compelled by circumstances to submit, they ought to use the following precautions: first drying should not be confined to one room, but to all the adjoining rooms. Mould, fungi, &c., should be rubbed and washed off with the greatest care. Fires of dry brushwood should be frequently lighted, and the windows should be opened. Muriate of lime or sulphuric acid should be put in different places to attract the moisture. To purify the air from other injurious matters, the following substances are recommended, chlorine, nitric acid vapours, fumes of sulphur, evaporation of vinegar, coarsely powdered and moistened charcoal put in different places, fumigations with the vapours of elder berries. For rooms already inhabited a solution of chloride of lime is the most proper substance. Drawers and other furniture ought not to be placed too near the damp walls, and if the latter should be covered with mould, they ought to be touched with a solution of chloride of lime. In addition, warm and dry clothes must be provided, and the bed must not stand too near the walls. Straw or feather-beds must be changed frequently, or exposed to the sun.—(*Dr. Riedel of Berlin, in Hufland's Journal.*)

PROGRESS OF ENGLISH, ITALIAN, AND AMERICAN MEDICAL SCIENCE.

[The following comprize the principal articles of interest to our readers in two recent numbers of the *Medical Gazette*.]

Record of cases.—Under this title, Mr. A. Ure has published two cases in which he used the iodide of potassium successfully. In the first case, the patient, a female, was affected with tubercular thickening of the upper lip, which was greatly enlarged and prominent; its external surface was the seat of superficial ulcers, for the most part covered with crusts. The affection commenced six months previously as a hard round swelling in the right side of the lip, unattended with discoloration. The swelling subsequently extended over the whole lip, and was always most conspicuous in the morning. Several indurated tubercles could be felt imbedded throughout its substance. The sores were healed by the topical application of a solution of nitrate of silver, after which, the internal administration of the iodide of potassium in small doses, effected a cure. The other case was one of periosteal thickening of the left ulna, with severe nocturnal pain. The iodide of potassium here also proved curative. It is not stated whether the disease had a specific origin. A case of diffuse cellular inflammation occurring in a drayman, a man accustomed to drink freely, and caused by the presence of rusty iron splinters, is next published. Free incisions were made; suppuration followed; and three splinters were taken out at different times; the man eventually recovered. The case does not present any novel features, and scarcely merited publication. In a case of nævus of the upper eyelid, M. Lafargue's practice of inoculation with croton oil was successfully practised. The punctures, five or six in number, were repeated twice, at an interval of a week; and the result was, the rapid diminution and withering of the tumor. In two cases of hæmorrhoids, one of them ulcerated, chromic acid was applied with the best effects. It caused acute burning pain, destruction of the diseased structure to a considerable amount, consolidation of the remainder, and permanent relief from the distressing ailment. Chromic acid is, as every chemist knows, a most powerful oxidizing agent, yielding half its oxygen readily to organic substances, and being reduced to sesquioxide. It is exceedingly convenient for application, inasmuch as it consists of a thick crystalline pap, which, when rightly managed, does not spread beyond the prescribed limits; and so soon as its erosive operation is finished, passes into the state of inert pulverulent sesquioxide. A case of gout was treated by the local application of the belladonna ointment, and rectified coal naphtha, with apparent success. The belladonna relieved the pain, but Mr. Ure attributed the cure to the naphtha. The concluding case is one of incontinence of urine, caused by the use (abuse?) of bicarbonate of soda. The patient, a man nearly 70 years of age, had been in the habit of taking half an ounce of the bicarbonate of soda every week to relieve indigestion. The urine afforded an alkaline reaction with red litmus paper immediately when voided, and evolved at the same time a faint ammoniacal odour. Its specific gravity was 1·010. It was deficient in uric acid, and in phosphate of lime; deposited, after being allowed to stand a few hours, ropy mucus and crystals of ammoniaco-magnesian phosphate. A few pus corpuscles were visible on microscopic examination. The urine became turbid on exposure to heat. Benzoic acid made into pills, with balsam of tolu, and capivi, in the form of capsules, were prescribed, and their use was attended with marked relief. Mr. Ure ascribes the incontinence of the urine to its alcaline condition.

Chorea and hysteria.—Dr. Blackmore has published several interesting cases of these diseases, of some of which the following is an abstract:—A female, aged twenty, who had suffered from severe headache, and various nervous symptoms, which were relieved by sponging the head, and the exhibition of citrate of iron, with a mild tonic diet, was attacked, after having had a severe sore throat, with hemiplegia of the right side, hysteria, and severe chorea, affecting the face and left extremities. When seen by Dr. Blackmore, the right arm was insensible and powerless, the leg also palsied in a slighter degree; the face affected with spasms; the eyes very protuberant, and the pupils dilated. She complained of pain at the occipital region and right temple; and the cervical vertebræ, and the lumbar and abdominal muscles were very tender: her sleep heavy, and manner fatuous; the tongue clean; the pulse rather low; the skin cold; the appetite voracious; the bowels had been torpid until regulated by medicine; the menstrua were regular. Dry cupping glasses were applied to the nape of the neck, the hair cut off, and an evaporating lotion applied to the head, purgatives with blue pill being also freely used, and a saline purgative exhibited in a bitter infusion. In a week the pain at the occiput was relieved, but the palsy remained; the chorea was stronger and more general; fatuousness increased, with fits of severe mental irritation, and violent hysterical symptoms; her speech much impeded; the pulse not disturbed; the extreme circulation low; the eyeballs more prominent; the pupils sluggish, but not fixed; the stools unhealthy, containing a quantity of black bile. On one day, when the aperient was omitted, the spasms were much worse. She was then cupped to six ounces from the neck, the occiput blistered, and iodide of potassium given in infusion of rhubarb. In a few days the fatuousness and the palsy were lessened, but she then complained of acute pain at the right temple, and at nights had strong fits of hysterical and maniacal excitement. The medicines afterwards acted

well on the bowels, and she ceased to complain of the head. By persisting in this plan of treatment, together with the conjoined use of the cold dash, the paroxysms became milder, the mental powers at times natural, the palsied limbs improved, but the spasms of the eyelids and jaws, the projection of the eyes, and severe pain at the right temple, continued. On knocking this part gently, the pain was increased, and spasm and swooning induced. An incision, three inches long, was then made along the edge of the right temporal muscle, down to the skull; and the scalp being very vascular, was allowed to bleed to six or eight ounces. She then became faint, a warm perspiration broke out, and the pulse fell from ninety-two to sixty-six. She afterwards slept calmly, and the next day exhibited the most decided improvement, expressing delight at the relief of pain. The wound was dressed to keep up suppuration; and croton oil with colocynth, and small doses of the bichloride of mercury with hydrocyanic acid, were given for ten days, during which her amendment was uninterrupted. The issue having healed, she again became worse, and continued to do so, in spite of leeching, blistering, purgation, &c., and in a few days there was more of a comatose tendency, with severe pain in the occipital, frontal, and left temporal regions; and slight percussion of the occiput again induced spasms of the left arm and leg, and hysterical sobbing; the left eye particularly prominent and vascular,—its pupil dilated; the face flushed; the pulse quick and full, particularly in the left wrist; the speech indistinct, and the tongue put out with difficulty; the left arm was now the palsied limb, the left leg also weak. The bowels had been freely purged with aloes and calomel, and the scalp extensively pustulated with the ointment. Tickling the soles of the feet had no effect on the functions of the spinal cord. A deep incision, five inches long, was therefore made along the left side of the head, and allowed to bleed to ten ounces, after which she spoke distinctly and sensibly. Evidence of effusion in the ventricles afterwards appeared, but was apparently removed by the influence of mercury. The patient ultimately became convalescent.—The next case is one of hysteria, apparently consequent on costiveness for several days. The spasms of the limbs, eyes, and respiratory muscles were extremely severe; the face black from the interrupted respiration; the pulse extremely low. She was bled to twelve ounces in the fit; the blood was very florid, and the clot soft. Purgatives and clysters produced several stools; but in a few hours the spasms returned severely, when ammonia and a fœtid clyster were given. In the course of the night the convulsions were so severe as to threaten suffocation; she had also acute pain at the occiput, and in the chest, with spasmodic cough, cold perspiration, and a very depressed pulse. On the spasms remitting, the pulse became natural. The hair was then cut off, ether and laudanum given in a clyster, and rubbed on the spine. In a few hours the spasms returned, with acute pain in the head, and throbbing; the pulse full. Senna and salines were given. The after treatment consisted of leeching, purgatives and salines. Copious purging of feculent mucous stools was followed by relief, and although the cure was interrupted by occasional relapses, the treatment proved successful. The cure was completed by stimulants, medicinal and dietetic. The disease in the third case seemed to be palsy of the hand, connected with suppressed menstruation, and was treated apparently with advantage by leeching the temples, purgatives, and electricity. The galvanic action relieved the palsy, but was seemingly productive of mischief by its over-stimulation. The patient became affected with severe pain in the side, for which she was bled repeatedly, and purged, the abstraction of blood ultimately causing syncope. The pain continuing in spite of these measures, the local abstraction of blood was practised by leeching, soon after which syncope returned, and was followed again by severe dyspnœa. She then complained of a great weight pressing on the sternum, taking her breath away, and again became insensible. The inspirations, at first 40 in a minute, then more and more convulsive, and never under 80. The pulse, at first 100, and fall, then rose to 150, and could scarcely be felt; the eyes became fixed; the countenance expressive of agony; some convulsive startings, similar to those she had been affected with during the use of electricity, were observed in the arms and chest during this paroxysm. On becoming more sensible, she felt the greatest difficulty in swallowing; the attempt seemed to excite convulsions in the gullet, and complete opisthotonos for two minutes; the very idea of swallowing seemed also to excite spasms. During this paroxysm, which lasted an hour and a half, she took 80 drops of laudanum with sulphuric ether; but as the ether seemed to excite spasm, it was exchanged for spirit of nitrous ether. A hot foot-bath then seemed to rouse the circulation; and on recovering she complained of pains in the side, palpitation, and a tendency to fainting, with anxiety at the præcordia, and headache. At 6 P.M. twenty leeches were applied to the epigastrium, with relief of pain, but with increase of the dyspnœa; and in an hour and a half a similar paroxysm to the former, but more severe, and lasting for five hours,—fits of syncope alternating with convulsions of three minutes' duration, and generally mitigated by ammonia to the nostrils, and finally relieved by repeated doses of laudanum and spirit of nitrous ether. In 48 hours twelve drachms of the former, with two ounces of the latter, were taken. Stimulants and anti-spasmodics were next used, with some relief, and as the paralysis continued, galvanism was again had recourse to, and purgatives administered. The consequence was, that the pain in the side returned, and a paroxysm of quick convulsive breathing, with loud moaning. The palsied hand kept on the precordia; the other and the general body, in convulsive movements; the pulse very quick, and at times imperceptible. Two drachms of laudanum were given in two doses, at interval of half an hour, without effect. At 10 p.m. the body and shoulders were drawn forward by tonic spasm; the respirations beyond 100 in a minute; three drachms of laudanum then given, in three doses, at short intervals. At midnight little improvement; two similar doses of laudanum, (making seven drachms in the course of the evening) with nitrous ether, were then given, and the paroxysm declined. The sleep was disturbed by dreams, and a narcotic influence remained for several hours. The next day, at noon, the affection of the chest had subsided; the pulse 88, respiration calm, thirst intense, and some headache. The use of nitrous ether was persisted in. A milder attack occurred in the evening. Opiates and purgatives were employed, and the patient got better of the hysteria, but the weakness of the hand—the original malady—remained, until she ceased to be under medical care. This case was not treated by Dr. Blackmore.

Hepatalgia.—This nervous disorder forms the subject of a paper by Dr. Allnatt, who, after quoting the brief but correct description of it given by Andral in his "Clinique Medicale," states that it is essentially a nervous disorder, and the diagnostic symptoms are well-marked. Although the pains accompanying hepatalgia may be as intense as those of hepatitis, and, in many instances, perhaps more urgent, they are not constant, but are at the outset, and frequently also during the whole progress of the disorder, paroxysmal, affording in the interval a complete immunity from pain. The pathognomonic signs indicative of inflammatory action of the liver, are pyrexia, tumefaction, great tenderness in the hypochondrium, frequent and strong pulse, thirst, furred tongue, and vomiting, sometimes of a bilious, and, at other times, of a dark-coloured secretion, as the substance of the liver more or less partakes of the invading disease. The bowels are irregular in their action, the evacuations presenting a great variety of appearances, according as the biliary secretion is more or less affected, and the urine is scanty and high coloured. In hepatalgia, on the contrary, these signs are invariably wanting; there may exist, indeed, constant pain and tenderness over the region of the liver, increased to a certain degree by pressure, but manifest exacerbations, even in the worst cases, occur, which are sufficiently indicative of its paroxysmal character. The functions of the organ may proceed uninterruptedly, as in its healthy condition. The tongue may be quite clean, or sometimes, in the centre, there may be a gentle creamy fur, and the urine is generally increased in quantity, and is of a lighter colour than ordinary: this is a characteristic symptom of many nervous disorders. The disease is generally complicated with peripheral neuralgia in some other part of the body. The treatment of hepatic colic, whether in its isolated or complicated form, is very simple, and merely requires the combinations which are found to be effectual in other cases of neuralgia. Mercury, as in tic douloureux, heightens the affection, increases the general irritability, and renders the system universally more obnoxious to the incursions of the morbid nervous sensibility. Carbonate of iron—the rage of the day—is, if possible, even more destructively pernicious. Gentle purgatives, combined with colchicum, ipecacuanha, and hyoscyamus, will seldom fail to work a speedy cure: and if the constitution have suffered from protracted unmitigated pain, alkaline vegetable tonics will effect that which we might in vain expect from the rough insoluble mineral preparations.

Insanity.—Dr. Blackmore states, that in a purely medical view, insanity presents itself under three forms:—1st, that with inflammatory symptoms: 2d, that in which fever is absent, the pulse firm, not quickened, sometimes slow; the features pallid and shrunk; the blood not inflamed: 3d, that of sudden and violent paroxysms, with a quick rapid weak pulse, a cold perspiring skin, an extremely pallid wild glistening eye,—the nervous form of mania. The diagnosis of this form from the second or the congestive variety of mania, is sometimes however extremely difficult, when it occurs in the course of an inflammatory affection of some organ in the chest or abdomen; an attendant hysterical symptom, or restless agitation and tremblings, in some cases help to solve the difficulty; but in others, the symptoms are merely delirium, sleeplessness and incessant talking, with a pulse not rapid nor intermittent, but gradually failing in power,—a state not always referrible to the previous abuse of stimulants, nor to severe depletory measures for the cure of the inflammatory disorder. In some cases digitalis has appeared to induce strong nervous delirium; but then the attendant sickness and irregularity of the pulse has clearly indicated the exciting cause. The second form comprises the most numerous, chronic, and embarrassing cases of insanity. The character of the symptoms is most deceptive; with a low pulse, and a cold skin, the most intense sanguineous congestion often exists in the brain; and the most successful treatment is founded on this view of the pathology of the case. In another case of remittent mania, the paroxysm was instantly cut short on making a free incision in the scalp. In this maniacal congestion, however, the contractile power of the vessels is soon exhausted, and nervousness or imbecility is easily induced, if depletory measures are carried far. In this order of cases, the oxide of zinc and camphor are trusted to, when free purging and cupping-glasses on the scalp would have been the best treatment. In the third form the obvious hysterical state, or the nature of the exciting cause—pain, grief, starvation, evacuations, digitalis, and spirituous liquors—easily suggest the successful use of cordials and opium. This form sometimes succeeds the first from the abuse of bloodletting and sedatives. These remarks are illustrated by the details of eight cases. The first is that of a female, who, after having suffered from habitual headache and vertigo succeeding epilepsy, was affected with cough, hæmoptoe, and pain in the side in the early stage of pregnancy, the relief of those symptoms being followed by a relapse of the brain affection with increased severity, amounting even to maniacal excitement. Bleeding, blistering, and active purging were had recourse to, and with evident benefit. The cerebral malady was clearly much diminished, but there continued violent pain at the top of the head, and the epilepsy returned. Towards the close of her pregnancy, Dr. Blackmore found her in a state of violent mania, after having suffered for ten days previously, from pain in the head, and sides of the abdomen. Bleeding and purgatives were again

had recourse to, but with no advantage; and the patient died in a fortnight after the invasion of the disease, having been unconsciously delivered of her burden, at an early period of the last attack. On examination of the body after death, the scalp was very thick: the skull very dense and heavy; the brain indescribably vascular; its blood-vessels amazingly enlarged and turgid; the pia mater extremely vascular; blood effused on it betwixt the the convolutions, so as to separate them. The medullary substance dotted with bloody points. A small portion of the surface of the right hemisphere presented the appearance of incipient gangrene; the choroid plexus was studded with albuminous points, and very vascular. The medulla oblongata and spinal cord were much softened. The cerebellum exhibited marks of inflammation and softening, most intense at the posterior part, where fluid blood was effused. Serum also was effused under the membranes and in the ventricles. The second case was one of puerperal mania, occurring in a young woman, who had been previously subject to nervous headache. It terminated fatally, in rather more than a fortnight. The *post-mortem* examination shewed evidences of greatly increased vascularity and effusion in the cerebrum. The third case is that of a lady who had nervous mania consequent on gastrodynia and disordered stomach, most probably from habitual neglect. She was cured by purgatives freely administered, and by the use of stimulants, to support her while under their influence. She had a subsequent attack afterwards, from which she recovered; but ultimately died of apoplexy, from effusion of blood in the brain, and diseased cerebral arteries. In the fourth case, a man 50 years of age, of intemperate habits, was affected with mania, from the sudden recession of erysipelas, for which he was bled freely on several occasions, and also purged, and ultimately recovered to a certain extent, both mind and body remaining feeble. The fifth case appears to have been one of delirium tremens, occurring as a consequence of large bleeding for pneumonia in a drunkard. When seen by Dr. Blackmore, he was in wild delirium, out of bed struggling violently with his attendant; the pupils dilated and fixed; the skin cool and in profuse perspiration; the pulse 140, and very soft; bowels costive. The treatment consisted in the use of purgatives, a blister to the nape of the neck, calomel and antimony, and a grain and a half of opium, on the bowels acting. The man recovered under the use of salines, and small doses of opium. In the sixth case, the mania was caused by a fall; it was treated by bleeding, blistering, purging, and tartarized antimony, with cold to the head. He finally recovered. A case of melancholia, the seventh in Dr. Blackmore's list, was cured by active and sustained purging, with the use of cordials, &c. The concluding case is that of a lady, who laboured under profound and habitual melancholy, with extreme torpor of the nervous functions, which had continued in spite of various remedies, and who experienced extraordinary relief on accidental uterine hæmorrhage taking place.

SURGICAL CASES FROM THE MARYLEBONE INFIRMARY.—Mr. Stafford narrates several cases from his practice at the Infirmary. The first is a bad case of compound dislocation of the ankle, which at one time induced him to recommend amputation, but the patient did not consent, and she ultimately recovered with an ankylosed joint. The next case is one of tetanus from an injury to the great toe of the left foot, and which presented some symptoms analogous to hydrophobia. The treatment consisted in leeching near the foramen magnum, and inunction of the spine with extract of belladonna. Turpentine enemata, purgatives, and Indian hemp were also ordered, but when an attempt was made to administer them, they were convulsively rejected. Hydrocyanic acid and morphia were next prescribed, but were equally rejected, and the patient died in twenty-four hours after the attack. The *post-mortem* examination did not show any remarkable appearances in the brain itself, but the base of the cerebellum, the tuber annulare, and the medulla oblongata, were much redder than natural. The medulla spinalis also, along the cervical vertebræ, was redder than it ought to be, but the rest of the spinal cord was healthy; the vessels of the arachnoid membrane of the base of the brain, and medulla oblongata and medulla spinalis in the cervical portion, were injected with blood; there was inflammation of the mucous membrane of the trachea, the larynx, and the pharynx. The narration of this case is followed by the details of two cases of phlegmonous erysipelas produced by wounds poisoned by a salt of copper, most probably the acetate. The treatment in each case was very protracted.

REVIEWS.

A Treatise on Poisons, in relation to Medical Jurisprudence, Physiology, and the Practice of Physic. By Robert Christison, M.D., F.R.S.E., Professor of Materia Medica in the University of Edinburgh, Fellow of the Royal College of Physicians, &c. Fourth Edition.

In his preface to this edition, the author regrets that circumstances, beyond his control have delayed its re-appearance beyond the period at which it was called for by the favourable reception of the last edition. In our preface to this short review, we must assign a similar reason for our delay in noticing this new edition of one of the very best of our standard works. If the work had been a new one, we should have contrived to bestow a more prompt attention to it, that we might have enabled our readers to judge of its merits; but the work of Dr. Christison has been so long before the public, and the former editions of it have so firmly established the reputation of the author, that we have allowed other and more pressing engagements to postpone for a time the performance of a very pleasant duty—that of pronouncing an unqualified eulogium.

The present edition is considerably larger than its predecessor. It has been increased by no less than a hundred pages, without, at the same time, being rendered unnecessarily diffuse. The rapid progress which toxicology is making, renders such an addition absolutely necessary. It may be useful to point out those parts of the work to which the greatest additions have been made, or in which the reader will find the greatest variance from former additions.

The introductory chapter, treating chiefly of the evidence of general poisoning, has been slightly increased in bulk, and on one of the most interesting questions which it comprises —the *modus operandi* of poisons—our author has greatly modified the views put forward in the former edition of his work. In the third edition, he thus sums up his views on this subject—"It remains indisputably established, that at last many poisons enter the blood, although doubts exist whether it is essential to their action that they pass with the blood to pervade the structure of the organ acted on." In the present edition we have the following summary—"On the whole, then, it may be considered as well established, that probably all, but certainly some poisons—of that kind whose topical action does not consist in causing destruction or inflammation of the textures to which they are applied—produce their remote effects solely by entering the blood, and through its means impregnating the organs which are acted on at a distance." There is little addition to the chapters on poisoning by the mineral acids and alkalies, but to the next chapter—that of poisoning by arsenic—considerable additions, as might be expected, have been made. This is rendered necessary by the many new tests, or modifications of new tests, which have been recently proposed, as well as by the unfounded assertion of M. Orfila, that arsenic is a normal constituent of the human body. These tests will be found accurately described, and the fallacies which attach to them clearly pointed out.

To the subject of poisoning by opium and hydrocyanic acid, additions have also been made, and the subjects are carefully brought up to the time at which the work was published. It would be idle in us to pass any encomium upon a work which has long been acknowledged as the very best on this subject existing in any language. We shall only, therefore, add, that the fourth edition has all the merits which have made the reputation of the former ones.

Remarks on Medical Reform, and on Sir James Graham's Medical Bill. By Lucius. London: Whittaker and Co.

We have received the second edition of this interesting pamphlet. It contains a clear exposition of the benefits to be derived to the Profession as well as to the public from Sir J. Graham's Amended Bill, and also some severe strictures on the inconsistency of the individuals who are endeavouring to create a factious opposition to a measure, which they must know to be a boon to the Profession. As a classical and clever composition, we can give it our strong recommendation. The following is the author's estimate of Mr. Wakley:—

Mr. Wakley has also vilified, in a manner calculated to shock the feelings of all reasonable men, many of the most distinguished members of these institutions, individually. It were a sorry and a sickening task, even to refer to the volumes he has written on the subject—but, with the view of proving the Finsbury representative an unsafe medical reformer, I refer to the leading article of his *Lancet*, May 19th, 1832, which reports the proceedings of an hospital dinner, in these words:—

"One of those farces denominated the annual hospital dinner was performed on Saturday week, and who, gentle reader, think you, was in the chair? Mr. Pennington, the ex-apothecary of Keppel-street, medical attendant for many years to all the *rotten-hearted Tories* resident in the north-west district of the metropolis." The venerable individual referred to, an Octogenarian, presided with great credit to himself, and advantage to his brethren, at the meetings of the Associated General Practitioners, held lately in London, for the purpose of negotiating with the Home Secretary, as to incorporating the General Practitioners of England into a distinct College.

NOTICES TO CORRESPONDENTS.

Mr. Wilton, of Whitehaven.—*The regulations respecting students will, in all probability, form a subject of serious consideration for the Council of Health. The whole matter is at present still sub judice, but we conceive that a student who commenced a definite course of studies in accordance with the prescribed regulations of the Society of Apothecaries, prior to the New Medical Bill becoming the law of the land, will be allowed to complete the course, and be eligible for examination. In answer to the second question, there can be no doubt but that the period of study directed for the student will be altogether independent of the apprenticeship.*

Dr. Higgins, of Paris, *writes to us in answer to the letter of "Justitia," which appeared in this Journal a short time since, respecting the Giessen diploma. Dr. Higgins condemns in strong language the sale of the German diplomas, and, acting on erroneous opinions of the present position of the Licentiates of the Society of Apothecaries, jumps at the conclusion that none but such would ever avail themselves of the privileges connected with a diploma obtained by purchase, and not by examination. He avers his belief that no member of a British College of Physicians or Surgeons would so throw away his money, adduces a somewhat improbable example to show the possibility of obtaining such diploma by forged documents, and concludes by reprobating the junction of dispenser of drugs and medical practitioner in the same person.*

If, by dispensing drugs, Dr. Higgins alludes to keeping a retail shop, where patent medicines, perfumery, combs, &c. are sold, we are willing to join in the condemnation he pronounces; but the respectable General Practitioner of the present day is often a man of as extended a medical education as the physician and surgeon, and equally aims at distinction and reputation. Dr. Higgins has clearly misunderstood their position in society and the profession, and is as evidently unacquainted with the education and station of the Licentiate of Apothecaries' Hall, or he would not have so rashly concluded that the Licentiate alone would seek for a purchased diploma. It is a singular fact, that not a few members of a British College of Surgeons, and a few Physicians also are honoured by the possession of these German diplomas.

A Five Years' Subscriber.—*A M.R.C.S.L. when the New Medical Bill becomes the law of the land may register as a General Practitioner, provided he be a member of the New Incorporation, and can prescribe, dispense, and recover his debts by proceeding at law against his debtors. The Physician and Pure Surgeon in future will not possess the latter privilege.*

X. [illegible]—*The party in question, we think, will have it in his power to register as a General Practitioner, his title being reserved by a special clause in the Act of* 1815.

J. A. M. *writes to us to complain that in a respectable county town (unnamed) in Ireland, there are two Practitioners, A. and B. A. is the dispensary doctor, and B. has been recently appointed vaccinator under the New Act. A. in consequence has taken to vaccinate the children of the poor at the dispensary, and has also announced his intention to vaccinate all applicants at that institution on a certain day, at a certain hour. This conduct is complained of, as likely to inflict a direct pecuniary injury on B.—and such it is, of course, very likely to effect. We are called upon by our correspondent as public Journalists, to affix the brand of reprobation on A.'s conduct, but we must first learn all the circumstances of the case.*

A St. George's Student.—*To answer all the questions our correspondent seems anxious to get, would require several pages of this Journal.—As we have already stated, the arrangements respecting Medical Students are still* sub judice, *and, in fact, it is impossible to return a definite answer to our correspondent's first query in the present state of the Bill. Certificates of attendance on Lectures and Medical and Surgical Practice at the Parisian hospitals, at least of such as are recognised by the authorities in France, will be received by the Edinburgh College of Surgeons; but, under the New Bill the diploma of that College will only be available in Scotland, and its possessor, if desirous of practising in England, will have to take an* ad eundem *degree at either the College of Surgeons or that of General Practitioners. For the curricula of the French and German Universities, we can safely refer our correspondent to the Medical Guide and Almanack for* 1845*: it is a very important and correct work, and every statement contained in it is founded on written communications from the respective medical institutions. Mr. Lee's work may afford the requisite information with regard to the Italian Universities, and we believe the American Almanack will supply a sketch of the Universities of the United States.*

A Subscriber.—*The qualifications for a Surgeon to a Poor-law Union have been defined by the regulations of the Poor-law Commissioners. We believe the license of the Society of Apothecaries to be usually requisite, but there are instances, we understand, of Union Surgeons who are not L. A. C. Foreign diplomas are admissible.*

Medicus *recommends that the new Incorporation be called "The Royal College of Licentiates in Medicine and Surgery," omitting all allusion to midwifery, which he says, is comprised in the two former. He considers it would be a great injustice done the English General Practitioner* at present in practice, *and who is fully qualified in medicine and pharmacy by license from the Hall, and in surgery by diploma from the College, if* any *practitioners* at present in practice *were permitted to register as General Practitioners, except those who can produce diplomas that they are* fully qualified *in medicine by degree of M.D. from a University or College; in surgery by diploma from a College of Surgeons; and in pharmacy by those incorporated bodies in the three kingdoms who are legally entitled to give diplomas in pharmacy at present. He would also consider it an injustice if any but a general practitioner, qualified as he has stated, should hereafter be eligible to fill those medical appointments in public institutions where all the departments are undertaken, and to be discharged by one practitioner, as, for example, dispensaries and workhouses. He concludes by stating, that if the mere* Irish *apothecary be allowed to register under the Act, it would be an act of injustice. We would beg to remind him, that the Irish apothecary follows a strict course of medical education, although not so extensive as that of the English licentiate, and he also undergoes a very severe examination for his license. It is high time that these petty distinctions be done away with. Medicus urges that the General Practitioner should be eligible for the license of the College of Physicians after six years' practice, and at thirty years of age. We fear that in operation this plan would prove ineffectual, inasmuch as the General Practitioner, unless a man of property, could not be sufficiently established in so short a time, so as to be able to depend on fee-practice alone. The recommendation that the new Incorporation of General Practitioners should be empowered to grant degrees in medicine and surgery, is futile. Sir James Graham could not grant such a power in opposition to the other colleges, which would suffer severely from his acceding it to the new incorporation. The objection to the licentiate apothecary taking equal rank in the new college with the holder of the double qualification, has been urged again and again; but the determination to introduce that equality was adopted after mature deliberation, and offers perhaps the only plan that can be brought forward without incurring the risk of greater dissensions than heretofore. The only way of obviating the objection would be by creating a class of fellows for the double qualification, and of members for the mere licentiate: and the impending ruin of the insensate Council in Lincoln's-Inn-fields should serve as a beacon against the adoption of a measure so fraught with discord.*

Mr. Fenning, of the Broadway, Hammersmith, *after enumerating the injurious effects sometimes produced by indulgence in lobsters, muscles, and other shellfish, refers them to the action of an overdose of iodine, which, he says, exists in large quantities in the shells of most sea fish, and in the red skin (epidermis) of the lobster and other parts of the different shellfish in variable proportions. He recommends, therefore, the removal of the red skin of the lobster, the excrementitious portion of the muscle, and the scaly coat of the shrimp, as a preventive of the evidences of surfeit.*

A Country Subscriber.—*A member of the Royal College of Surgeons of Edinburgh, commencing practice in Ireland under the new Bill, will be enabled to take an* ad eundem *diploma in the Irish College without examination, which will enable him to practise in all respects as a General Practitioner. He will have to pay a fee for the diploma.*

Inquisitor *is inadmissible.*

A. T.—*The requisition calling a meeting with the view to force a factious opposition to the National Association has not been so numerously signed as it has been pretended. The paper left at Renshaw's received only twelve signatures, several of which will be thought, perhaps, inadmissible, as being those of country practitioners, unable to attend the meeting. The requisition at Highley's, in Fleet-street, had sixteen names only attached to it: and that at Turner's, at Hackney, received* one *name. If the remaining six medical booksellers obtained signatures in a corresponding proportion, and there is no reason to believe otherwise, what becomes of the upwards of* one thousand *names said to have been attached to their highly-trumpetted requisition?*

The communication of Dr. Sutherland *is important, and shall be noticed early.*

Mr. Hillier *assures us that we were in a double error in reference to his adhesion to and desertion of Mr. Wakley. He* did *know him personally before the movement, and is an ardent admirer of him now. We had imagined to have heard Mr. Hillier say, at the last meeting of the National Association, that he did not know Mr. Wakley personally before the movement, and we thought we heard him authoritatively declare that the "movement" itself was a* "factious" *one, and that he thenceforward deserted it. We fancied also that Mr. Wakley responded to him before that large public meeting in a very offensive manner. We were of course in error, and now that Mr.* Hillier *tells us so, we are happy to express for our mistake our sincere regret.*

The cases of Mr. Thomas *shall be published.*

Mr. Levison's *communication has been received.*

A Manchester Student *is informed that terse, practical remarks, in illustration of the cases, will doubtlessly add to the value of the reports in the estimation of the arbitrators.*

A. X.—*The testimony would be most useful, but to be so must be immediately forthcoming.*

A Handsome Portfolio *for holding the* "Medical Times,"*—very desirable to those who would keep the numbers clean for binding, and easy of reference—may be had, by order of any Bookseller, or at the Office, price* 5s.*—An allowance is made to the trade.*

THE MEDICAL TIMES.

Saturday, June 14, 1845.

Delenda est Carthago.

There is no understanding the Council of the College of Surgeons. It is evident that their past maltreatment of the profession has originated in some mysterious infatuation. They seem neither to know themselves nor the profession, nor to have the most remote conception of what is reasonable in policy or right in principle. Their errors are matters far more for pity than for censure. Their late manifesto, published by us some time since, was about as absurd a document as lunacy itself could have concocted. With the policy, and no doubt the wish, of conciliating, there was hardly an expression indulged in which had not a direct tendency to exasperate and make their members more hostile. They even sought a defence for their assaults on the vested rights of their members, in the fact so gracefully admitted by them that they had been deluging the profession with quacks and felons, and had been certifying thousands of persons as *surgeons*, to the public, who were scarcely competent to perform the commonest "ministrations" of the medical art. The statement we now give is marked by a similar spirit of wrong-headedness. Written with an elegance and force that we should be the last to deny, the elegance and force stand forward as the Council's greatest antagonists. It is difficult to conceive more clever advocates *against* themselves. The Council's part in policy was about receiving some little protection from a delusion carefully taught, that the proposed New College would degrade surgeons more than even their present disgraceful relations with the College of Surgeons. The delusion was acquiring strength; it was interfering with that unanimity which above all other things was requisite to secure the promised boon, and forthwith comes this learned Council to blow the delusion to the winds, and prove to General Practitioners that if they would wish avenged the insults which they have received from this mysterious Council, now is their time. Maltreated, contemned, libelled before the public, and directly addressed in language the most contumelious, the injured members, now receive the unsuspected assurance of their very wrongdoers, that the Minister offers them, in a New College of their own, privileges, powers, and distinctions which they never could have received in their former relationship with the Council! We had intended to have submitted to our readers an elaborate article, with the direct intention of shewing the baseless nature of the delusion attempted to be practised on them, by persons professing an anxiety for their dignity and well-being; but the document of the College so

completely anticipates all that we could have alleged, with an authority so irrefragable, that for our leading article this week we will stand indebted to the twenty-four Rulers of the Royal College of Surgeons of England. If these Gentlemen estimate the boon of the New Incorporation to us at so high a price that they will go all lengths in opposing it, it would be odd indeed if we should show the justice of the degradation we have received from them, by lending a helping hand to their policy. If the opportunity be lost, if Sir James Graham's intentions are allowed to fail us through our own supineness; if we allow him to succumb a victim to the energetic resistance of our enemies, we deserve all that we have suffered, and may safely place at our own doors the responsibility of our continued misgovernment. Here is the well-timed

STATEMENT OF THE COUNCIL OF THE COLLEGE OF SURGEONS.

At a Meeting of the Council of the Royal College of Surgeons of England, held on the 5th of June, 1845, present,—Sir Benjamin Brodie, Bart., President; Mr. Cooper, Mr. Lawrence, Vice-Presidents; Mr. Keate, Mr. Vincent, Mr. Guthrie, Mr. Andrews, Mr. Briggs, Mr. Travers, Mr. Swan, Mr. Stanley, Mr. Green, Mr. Callaway, Mr. Liston, Mr. Arnott, Mr. South, Mr. Welbank, Mr. Cutler, the following Statement, relative to certain parts of the "Bill for regulating the Profession of Physic and Surgery" as amended in Committee of the House of Commons on the 7th ultimo), was unanimously approved and adopted:

The Council of the Royal College of Surgeons of England, after considering the Amended Bill as fully as the difficulty of ascertaining the exact meaning of some of its provisions permits, beg leave to submit some observations, which, as offered by those whose duty it is to guard the interests of the surgical department of the profession, will not, they trust, be deemed unworthy of serious attention.

The Council respectfully represent that the new Charter and Bye-Laws of the College of Surgeons were framed in conformity with the propositions submitted to them in the form of "Heads of a Bill for regulating the Practice of Medicine and Surgery," and that they assented to the change which the Charter effects in the constitution of the College, as an essential part of the measure then contemplated for the regulation of the Medical Profession. But they are prepared to show that the Amendments, as proposed in the Committee of the House of Commons, differ in principle from the Bill, and from the original Bill, of which the heads were submitted to this Council, and that they are inconsistent with the Charter and Bye-Laws founded* upon those "Heads."

The Council had every reason to believe that the change in the constitution of the College, was a pledge of the continued support of Her Majesty's Government; but they find that one of the principal features of the amended Bill is that of providing for the institution of a College of General Practitioners in Medicine, *Surgery*, and Midwifery. Now, although it was not unknown to the Council of this College, that the subject of incorporating the General Practitioners was under consideration, they imagined that the object of the incorporation was to provide for the more efficient performance of the duties confided to the Society of Apothecaries; and they cannot help expressing their surprise that, without any official communication to those most affected by it, a new College is about to be established, which is intended *not only to embrace Medicine, Surgery and Midwifery*, BUT TO BE CO-ORDINATE IN PROFESSIONAL RANK AND IMPORTANCE WITH THE EXISTING COLLEGES OF PHYSICIANS AND SURGEONS. It might be an invidious task for the Council to investigate the probable results of a measure which will entirely change the relations of the several branches of the profession, and confound distinctions hitherto recognised as beneficial to the community; but they feel bound to state their deliberate conviction, that in the framing of the Amended Bill the interests and privileges of the College of Surgeons, and its claims to legislative protection, founded on the undeniable ground of public utility, have been unhappily overlooked.

That the proposed College *is intended to be co-ordinate in professional rank and importance with the existing Colleges of Physicians and Surgeons will be seen by Clause* 14, in which the style of the New College is recited as the Royal College of General Practitioners in Medicine, Surgery, and Midwifery, of England, and its Members are described under the title of Fellows. Thus for the first time will *every General Practitioner be presented to the public under the title of Fellow*, a title which was intended to designate the highest professional qualifications of Physician or Surgeon, but which here appears to *imply that the General Practitioner combines the highest qualifications of both Physicians and Surgeons, conjoins* their functions, *and superadds* those of *the Professor of* Midwifery, but *discards the characteristic designation* of Apothecary. The Council believe that the proposed title of Fellow of the Royal College of General Practitioners does not intelligibly describe those who, combining the practice of Medicine, Surgery and Midwifery with that of Pharmacy, compound their medicines, and supply medical aid and advice at a moderate cost; or that *it describes them under a title which can scarcely fail to mislead the public in estimating their true character.*

In the absence of the draft of the Charter to the proposed College, this Council have no means of forming an opinion as to the precise powers and privileges intended to be conferred on the new body, but they think enough appears on the face of the Amended Bill to show that it is proposed to establish a Court of Examiners, who are to have the exclusive power to grant Letters Testimonial of the fitness of persons to practise as General Practitioners, and who will therefore, it may be presumed, examine the Candidates in Surgery.

It is true, indeed, that by Clause 17 a provision is made for a preliminary examination to be conducted by a joint Medical and Surgical Board, including six Surgeons chosen by the Council of the College of Surgeons; but it is equally true that the Candidate for the diploma which is to enable him to practise Surgery at the age of twenty-two years, or at any later age,—unless he become a Fellow of the College of Surgeons,—will be subjected to a second examination, may be rejected, and can only obtain an authority to practise Surgery through the Royal College of General Practitioners. *It is plain then that, by the Amended Bill, the College of Surgeons will be subordinate to the College of General Practitioners* in those functions for which the College of Surgeons was especially instituted, and that the Surgical Examiners at the Joint Board may be placed in the degrading position of having a Candidate whom they had declared duly qualified, rejected at the subsequent examination by General Practitioners. It is also, to say the least, a singular feature of the Amended Bill, that the legally constituted Court of Examiners of the College of Surgeons should have been passed by, as wholly undeserving of notice, in arrangements which demand services for which they must be supposed peculiarly fitted. And it is worthy of remark, that the preliminary examination which is not required in Scotland or Ireland, is made imperative on those who desire to become Surgeons in England, and that those who have passed a single examination in Scotland or Ireland will be entitled to all the advantages of English Practitioners, who have undergone a double examination.

It will be seen from Clause 32 that Registered General Practitioners are to be deemed to *all intents and purposes qualified Practitioners of Surgery*, and *capable of filling any surgical appointment in any local or public institution.* And by comparing Clause 15 with Clause 14, we learn that the qualification being in each case the same, namely five years of professional study, the General Practitioner is to have the advantage of obtaining at twenty-two years of age the legal authority to practise surgery, which is withheld from the Surgeon till he is twenty-six years of age. The probable result, therefore, of this part of the Amended Bill will be, that the object of the College of Surgeons—in instituting, with the concurrence and approbation of Her Majesty's Government, the Fellowship of this College as a higher grade of Members of the Surgical Profession, in order to excite a spirit of emulation and to promote a higher and more extended education—will be defeated, as far as legislation can accomplish it.

By Clause 15, every Registered Practitioner will be entitled to be registered as a Surgeon, provided he has been twelve years in the practice of Surgery, and shall have received Letters testimonial from this College of his being duly qualified to practise as a Surgeon. The Council of this College, therefore, cannot but think that the amended Bill is calculated to discourage the attainment of the Fellowship in the manner prescribed by the Bye-Laws of the College, which require a prolonged course of laborious studies; since, *according to the provisions of this Clause, the General Practitioner is already completely a Surgeon in all his functions*, qualifications and privileges. And they perceive that the operation of the above Clause will be direct and certain in taking away all inducement to obtain the Diploma of this College, and thus in limiting its Members to those who were designed by the Charter to form only the higher grade of Fellows.

Thus, under hostile attacks, devoid of any reasonable ground, and unsupported by any rational argument, is the Royal College of Surgeons—recently re-chartered by Her Majesty for the promotion and cultivation of surgical science, and not charged as unfaithful to, or incapable of, its high functions—thus is the Royal College of Surgeons of England in danger of being sacrificed to the views and wishes of those who hope to annihilate it by the establishment of a rival College of Surgeons under the specious name of a College of General Practitioners in Medicine, Surgery, and Midwifery. It will not, however, escape notice, that the proposed Corporation, in assuming the name of a College *has no legitimate claim to a title, properly used to designate any institution, of which the essential object is the promotion of science and learning.* In the case of Physic and Surgery, the claim is precluded by the existence of the Colleges of Physicians and Surgeons; and in that of Midwifery and Pharmacy, the cultivation of each

would properly devolve upon a special Institute, the intention of which should be guaranteed by the appointment in the first instance of the most distinguished Professors of the science.

That sufficient reasons may exist for an incorporation of General Practitioners, the Council of the College are as little prepared now to deny as when in reply to the National Association of General Practitioners they said,—"With regard to the proposed incorporation of the General Practitioners as a separate body or College, the Council have as little the wish as the power to prevent them from obtaining a Charter, and *would offer no objection to the incorporation of a body for the performance of the functions hitherto executed by the Society of Apothecaries.*" The Council of this College do not object to an incorporation of General Practitioners, if it should be found necessary, in order to fulfil purposes of public utility which cannot be accomplished by the two existing Colleges; but they protest solemnly and urgently against such incorporation in a form which, in assuming a name and powers to which it has no legitimate claim, invades and annuls functions vested in the Royal College of Surgeons.

Whether the separate incorporation of the General Practitioners would best promote their own interests and the interests of the Medical profession at large, is a question of doubtful solution. In considering that question, however, it is important to remember, that by the provisions *of the recent Charter and Bye-Laws* the union of the General Practitioners with this College may be obtained by means which cannot fail to raise their qualifications. The Fellow of the College who has obtained his degree at twenty-five years of age, after a liberal and extended education, will not be precluded from practising, in conjunction with Surgery, the other branches of the profession; and a General Practitioner, being a Member of of this College, who may have been deprived of the opportunity of obtaining his degree at twenty-five, may become a Fellow after having been in practice for a definite number of years. And it may be added, that all the *Fellows*, under the conditions of the Charter, *are* eligible to the Council, and to the highest honours of the College.

In conclusion, the Council, appealing to the estimation in which the diploma is held, and the high character which English Surgery has attained, in proof that the rights and privileges conferred on the College by Royal Charter have been faithfully employed for the intended purpose of advancing the science of Surgery, hope and trust that the services and claims of the Institution will be fully considered before any legislative measure shall be adopted for the regulation of the Medical Profession; that no new Institution will be authorised to assume a name implying functions hitherto entrusted to this College, nor be empowered to interfere with or supersede it in its legitimate province of testing the qualifications of Surgeons, and conferring on them the legal authority to practise Surgery.

By order of the Council,

EDMUND BELFOUR, Sec.

"Locus animo debent aliquando dari,
Ad cogitandum melior ut redeat sibi".—Phædrus.

"Hæc scripsi non otii abundantia, sed amoris erga te."—Cicero.

The only other remedy against the diuresis of trepidation, of whose efficacy we can speak from personal experience, is camphor. We have known many instances of its good effects, when it has been taken sparingly and at intervals. It possesses, to some extent, the physiological properties of opium, and, like it, acts against the excitement of the kidneys, chiefly by its stimulant influence upon the physical and intellectual organs. A moderate dose of camphor, say five or ten grains, increases the force and frequency of the pulse, gives fire and animation to the eye, diffuses a warmth through the frame, and adds a temporary impetus to imagination and memory. It is more diffusively stimulating, and less directly intellectualizing, than opium. Besides these obvious properties, which are quite sufficient to account for its service in the emergency we mention, it seems to exert a *specific* effect upon the urinary apparatus. Both the kidneys and the bladder are the subjects of its influence. In irritation of the former organs, whether arising spontaneously, or from the action of certain diuretics, as cantharides, turpentine, nitre, or juniper, it is a most serviceable remedy. We have seen it allay the strangury, the agonizing back-ache, its concomitant retraction of the testes and sciatica, the abdominal pains, and nausea, like a charm. And let us tell you, worthy reader, be you medical or otherwise, that the safest, surest, and most convenient way of administering camphor under such circumstances, is to take three or four lumps of the size of a horse-bean, put them into a gallon bottle three parts full of rain water, agitate the whole vigorously for ten minutes, and let the patient drink of it at his leisure. The epithet, *cito, tute, et jucunde*, applies to this form of exhibiting the drug, a thousand times over in preference to any other, when its peculiar action upon the kidneys is called for. In like manner, and to an equal extent, is it of service in that irritability of the bladder which renders retention of urine either difficult or impossible. It would seem to possess then, and there is reality in the appearance, a power even greater than that of opium, in correcting or counteracting any temporary excitement of the urinary organs. For as we have said, additionally to its seemingly *specific* action, it is a stimulant of the nervous system, as well in its physical as in its intellectual relations.

We have often known camphor taken, and with good effects, as a mental excitant, prior to the occasion of public speaking. We have ourselves experienced its benefits. But with it, as with opium, an overdose is capable of producing unpleasant, and it may be, ridiculous, consequences. In the story about to be related, the writer was one of the subjects of illustration; but to avoid the inconvenience of discoursing in the first person, the narration will be as if of two individuals of our acquaintance. Some six years back, on the occasion of the annual election of presidents at the Royal Medical Society of Edinburgh, the two gentlemen we allude to, were considered pretty certain of an elevation to the distinguished chair. They had dined together, had ate and drank sparingly, and in journeying to the Society's Hall, felt, naturally enough, the qualms peculiar to anxiety. One stepped into a druggist's shop and purchased a drachm of camphor which he divided with his friend, telling him at the same time to use it sparingly, and at most not to eat above half of it. The advice however was disregarded, as well by the giver as the receiver, for during the excitement of the election, each man unconsciously swallowed his half drachm of the drug. They were elected presidents, and one of them being at the head of the poll, had shortly, by virtue of seniority, to take the chair. It was as he re-entered the room, to receive its plaudits and its highest honour, that an agonizing pain seized his head, darting through his temples, and as it were transfixing his brain. A thousand lights flashed before his eyes, and his ears rung with strange noises in which he recognized none of the welcomes familiar to friendship. The ground reeled under his feet, and it was with difficulty he reached the pausing place of his ambition. As he viewed the audience from his elevation, a crowd of faces seemed curiously merry and laughing, and their joy wore to him so strange an aspect, that it was not without effort he persuaded himself a delusion had stolen over him, and the fair reality was a flattery and a cheat. After a convenient interval, he rose to return the usual thanks, and make the accustomed promises. Very unusual with him, his lips faltered, his cheek turned pale, the anticipated eloquence was a mumble of gratitude, he bowed a confused acknowledgement, and resumed his seat seemingly overwhelmed with the obligation of honour. Luckily, his dilemma was attributed to modesty—a weakness he had never been charged with before. False ideas and troubles crowded upon him as he sat, and after some minutes' interval he left the room. The first object he encountered in the open air was his friend, who, likewise under the influence of the drug, was crying piteously, and vomiting at intervals—he was perfectly hysterical. The two men, who, of all others, should have been joyous that night, were the victims of a miserable narcotic delirium. As the evening wore away, they slowly revived, but its *finale*, in the famous supper peculiar to the occasion, was if possible more remarkable than its outset. The two leading presidents, upon whose faces joy should have sat as substantially as if it were stereotyped, figured, like mutes at a funeral, with solemn faces and a seeming grief. The assembled guests, like Augustus with his Horace and Mars, sat *inter suspiria et lachrymas*, between sighs and tears.

Now that we have finished this department of our subject, we must turn back to the consideration of tea, and of the other instances of its diuretic action. We love the serials of the schoolmen, and follow them as faithfully as we can.

Singula quæque locum teneant sortita decenter.

Horace said as much of poetry, but it is greatly more fitting that it should be said of prose, especially such as is to be made a vehicle for the conveyance of facts, be they those of entertainment or instruction. It will be remembered that, when we began upon the diversion we have just terminated, we were saying that not only should tea be avoided on the occasion of long journeys or of public speaking, but that it should never be taken to any extent at bed-time, from its tendency to produce nocturnal diuresis or perspiration. These unpleasant consequences, which are often the occasion of serious alarm, are in many instances traceable to an indiscriminate use of this evening beverage. And we would particularly caution the inexperienced practitioner to weigh well the extent, and the probable effects, of its employment before passing an opinion upon circumstances that are frequently connected therewith. A want of this caution and foresight has been a source not only of painful apprehensions and fears on the part of patients and friends, but of a final loss of confidence in their medical adviser. We were intimate some years ago with a student, a promising man, who from a state of tolerable activity, sturdiness, and strength, emaciated by degrees until he became but a shadow of his former self. He lost his spirits and his habitual merriment, and the only remnant of his old jocosity and playfulness was a melancholy comparison of his frame

with that of Gonelas horse, of which it was said, *tantum pellis et ossa fuit.* He desponded for some weeks, shunning society and friends, and the opportunities of pastime, but at last confidentially communicated the annoyance of his modesty, and the enervation of his manliness, viz. a fancied diabetes. It troubled him chiefly during the night, when he was often compelled to rise three or four times. This was doubtlessly a great cause of his exhaustion, but perhaps an inferior mischief to the mental agony which attended it. After a careful scrutiny of his case, the actual existence of diabetes, in either of its forms, was doubted, and a further enquiry made as to the probable cause of his anomalous condition. It was then discovered, that to facilitate his studies, he was in the habit of drinking large quantities of tea late in the evening. So habituated was he to it, that even on a return from a party, he would take more or less of his accustomed potation before going to bed. He was advised altogether to abstain from the practice, and in place of it, to sup on gruel, containing a small quantity of brandy. From the time that he changed his living he began to improve, and in less than a month he was not only free from ailment, but anxious after a prize contest, in which, despite the effort it cost him, he came off victor. It is not necessary to say, that he ever afterwards viewed tea with a very jealous eye. A somewhat similar case occurred to our notice not long ago, in the person of a gentleman, who, because of losing his flesh, and urinating more copiously than common, fancied himself the subject of diabetes. Knowing well, how peculiar habits of living will determine a false evidence of this kind, it concerned us, before examining his secretion, or enquiring particularly into his leading symptoms of distress, to question him closely about what he ate and drank. He was a merchant, living a few miles from town, and for convenience sake took breakfast and tea at home, and dined at a chop-house. We learnt, that he drank *so many* cups of tea before starting in a morning, and *so many*, after returning at night. These several cups added together, and estimated by a known measure, were found to amount to about a gallon daily! Consider further the items of wine and soda-water, for neither was much neglected, and we find a pretty quantity of fluid swallowed during waking hours. Of course it must pass off, and more likely through the kidneys than any other outlet—and one would think the profusion would be no surprise, considering the fertile cause of it. But so it is—men are much more apt at complaining of their troubles than of the personal occasions which they give of them. They will charge Providence, Nature, Chance, anything, with the cruelty, rather than themselves with the crime. They lose sight of their responsibility in their suffering, and seek an ideal cause in the very face of the only true testimony against them. They neither regard excesses as errors, nor their consequence as the punishment due to profligacy. So sensuality becomes paramount, and so are its votaries made victims. Even if the sin be at length abandoned, the act is considered, not one of selfishness, but of sacrifice. What is the cold obligation of duty, and a dictate from motives of personal safety, is paraded as a deed of devotion, having the origin and the object of virtue. Such was the case before us. The first difficulty, and it was no trifle, was to persuade the invalid that his gratified appetite was his greatest disorder. Like Matthews in the play, he thought what he drank could hurt no man. Persuasion at last prevailed with him, and he consented for a time to limit his amount of indulgence; but he wished it to be understood, that the penance was an amiable concession on his part, and no indication of a change in his old belief, that what he ate and drank neither disagreed with, nor disgraced him. Of course, under an opposite regimen, he soon became a different man. But though he recovered his health, a gratitude for its restriction was absorbed in the solitary feeling, that he possessed wonderful firmness and philosophy to curtail his epicurism, and contribute to his own cure.

TO THE PRACTITIONERS OF MEDICINE AND SURGERY IN THE PROVINCES.

Gentlemen,—My attention has been directed to a document emanating from a committee of Surgeons, sitting at the Freemason's Tavern; and purporting to be a list of resolutions to be proposed at some subsequent meeting, of which the date is suppressed.

I do not intend to comment upon this circumstance, nor to raise any factious objections to the constitution of this, or of any other committee, since it is evident to every man who has the least acquaintance with public business, that the first committee being always the agents and promoters of any scheme must be self-appointed, and the second is usually the reflex of the first.

Nothing is more easy than for a man of sagacious intellect, and oblique moral perceptions, to surmise plausible objections against the purest motives and conduct, and when he has collected a sufficient number of supporters, to assume—first as probable, then as certain, and afterwards as an undoubted and acknowledged fact, the mere suggestions of his own perverse imagination. Public opinion is often, to some minds, a sanction for deception and a justification of falsehood.

Error is progressive in its nature; faction is seldom giant-born—at first scarcely daring to show its head, it will by encouragement rapidly reveal its proportions; a wary opponent does not at once declare the full limit of his intentions, he conceals his hatred under the mask of sincerity—like a blind man groping in unfrequented paths, he points his foot in various directions before he plants it; at length public opinion gives him a directing voice, his character suddenly changes, he moves with more confidence and spirit; from being the objecting friend, he becomes the friendly objector, and ends as the rancorous, uncompromising, and deadly adversary. This has been the course and event of the present hostile movement, but I trust that your good sense will enable you to determine your own position in this struggle, the true nature of your interests, and the value that should be assigned to services which, whether well or ill-intended, can lead to no other than dangerous and lamentable results.

Had I not an implicit reliance in the innate sound judgment, and freedom from party bias and prejudice of my professional brethren, I should not have hazarded the publication of my first letter; the satisfaction which that has given has induced me to publish a second; and I am further animated to this step by the conviction that the amended Medical Bill has been wrongly understood and falsely interpreted, to the stirring up of suspicions, animosities, and dissensions among us.

While this opposition was confined to the constitution of the committee in Hanover-square, it was ridiculous and unsuccessful; and it was not until this committee adopted the present Bill, that a small portion of the profession deemed it expedient to enter the ranks of the opposition, and to advocate a policy already abandoned as useless, and branded with discomfiture and disgrace. The cry against a permanent committee is now changed to enfranchisement in the College of Surgeons, and it is contemptuously believed that the Profession are so inconsistent and puerile, that after voluntarily subscribing for the establishment of a New College, they can be induced, by a mere beckoning of the hand, to forego their principles, to stultify their judgments, and to revoke their former enthusiastic and solemn pledge. Resent such an injurious opinion of your intelligence by an independent and manly assumption of your right of private judgment. Do not be led away by cunning pretences, jesuitical casuistry, nor wily professions; but read, reason, and decide for yourselves.

Gentlemen, the document I have already alluded to, contains a circular letter, in which your assumed wrongs are artfully and energetically stated; and in which you are required to resist the formation of a "New Apothecaries' Hall." What nonsense is this! Nothing but a spirit of inveterate hostility could have incited any body of men to stigmatise by such a name, an institution which will embrace all the more respectable and useful men of the Profession, which will embody all the best principles for which medical reformers have ever contended, which will be the exact and perfect reflex of the social position and earnest desires of the Profession, and which will be established in accordance with their almost unanimous demand.

It is also said, that "Surgeons are to possess no legal right to recover at law *any* charges for their professional services." *As Members of the College of Surgeons*, certainly not; but have they ever been able to do so? The Bill does not aggrieve them in this respect. But the sophistry of this statement is very apparent, since it infers, *what is not true*, that an individual practising surgery will be empowered to recover charges for professional attendance—nay, more, that the present surgeon is also excluded from this privilege:—the reverse is the case.

Since I have undertaken the responsibility of advising my professional brethren on the disputed points of this Bill, I have carefully examined its clauses, and I now affirm boldly, and without fear of contradiction, *that the present Surgeon will be entitled to register in two classes*, viz., 1st, as a member of the Royal College of Surgeons, and 2nd, as a fellow of the Royal College of General Practitioners. I am aware that the hon. member for Finsbury says differently; I am aware that the Committee of the National Association has sanctioned an opposite opinion; yet what is the truth?

By clause 38, a penalty attaches to any individual who shall assume any "*title* belonging to *a class* in the registry *to which he does not belong*." Observe, the penalty is for assuming the *title*, and that only; it does not interdict, in any way, a double registration, and hence the assumption of double titles. The restriction is included in the division of the sentence "*to which he does not belong*." If a person belong to two classes, he can legally assume two titles, but he cannot assume a third title in which he is not registered. This is apparent to the lowest intellect.

But I am told that it is not the intention of Sir James Graham to allow a double registration. Who knows this? And suppose it is not, the next Secretary of State may entertain a different intention from Sir James Graham, and at all events, the Act of Parliament is clear and imperative, and will annihilate the specious intentions of any Minister of State.

The qualifications for registration as Physicians, Surgeons, and General Practitioners, are stated in different clauses, and I maintain, that in accordance with the letter and spirit of the Act, any man *having the qualifications* is entitled to registration in either, or in all these classes, without any hindrance or reservation. The law must be acted on;—there is no discretionary power referred to any Council or Examining Board;—there is no clause in the Bill *prohibitory* of a double registration, or in any sense implying the suppression of one title upon the assumption of another; it is no where, for example, said, that when a General Practitioner registers as a Physician or Surgeon, he ceases to be a member of the former College, and invalidates his claim to the registration.

Then, gentlemen, how can it be said, with truth, that Surgeons will not be able "to recover at law *any* charges for their professional services," when every Surgeon who pleases, may become a member of the College of General Practitioners, *and reap*

the double advantages of a double registration? It is the Surgeon, I affirm, who will more peculiarly benefit by the provisions of this Bill. Do not mar these advantages by factions, intrigues, and clamorous denunciations.

Let me intreat of you, gentlemen, to judge for yourselves—to shut your ears against inflated declamation, and verbose harangues—full of shallow sophisms, scurrilous cognomens, and reckless assertions—but void of truth, candour, and sincere argumentation. With the double registration, all present Surgeons will be enabled to retain their title and offices; and will be endowed with all the privileges and immunities of General Practitioners. I still, however, hold, that future Members of the New College should be denominated Surgeons, or be declared qualified to hold offices *as Physicians and Surgeons* to our public institutions, notwithstanding any local bye-laws to the contrary.

Once more, gentlemen, the charmer, whoever he be, is charming you wisely,—he is inviting you with a gracious solicitation to augment his ranks,—he is artfully caressing the most sensitive sympathies of an Englishman,—he is not only indulging you with a breakfast, but he is dressing it up in the most approved style to tempt the most reluctant appetite, and gratify the most fastidious taste;—you are fond of the *principle of representation*,—you have contended for it with a spirit and vigour that have done you honour, but it seems that you have been hitherto working in happy ignorance of its nature and appliances—the political mare's nest has at length been alighted on—the labours of political alchemists have at last discovered the philosopher's stone—the squaring of the circle has been achieved, and the representative principle was nothing but a quackery, until the Solons of the Freemason's Tavern taught you how to exercise it. Although there may be a committee sitting in London, with the full assent of the members, all whose rights and interests are the same, yet this committee does not represent the wishes of the consenting body:—it is required that an ephemeral association shall enter into all the details and tumult of a parliament election! Is this necessary? Is it not uncongenial and foreign to the nature and character of our profession? In general politics, there are numberless distinct and antagonistic local interests to represent; local elections are therefore necessary for public security; not so, however, in the case of the General Practitioners of medicine in this country, whose objects and interests are identified; and district elections are, consequently, needless and inconsistent with the first principles of legislation. It is a mere expedient of political fencing. If the representative principle thus exercised by an ephemeral body were beneficial, it would, of course, be more useful in a permanent corporation where there are interests more vital to maintain, and privileges more valuable to fortify and support; yet you know that this system, as a local representation, would be perfectly absurd.

At the conference of a deputation with Sir James Graham, when I was present, the hon. Member for Finsbury referred to this very system of representation; when Sir James Graham observed—

"I suppose you would like to have a sort of Medical Parliament in London?

Mr. Wakley.—Yes.

Sir J. Graham.—Then I candidly tell you, *that I never will consent to it.*

Gentlemen, I am one of yourselves,—my interests are in common with yours, I am not leagued with any journal or party;—as an independent man, I appeal to independent men, and as the declarer of unvarnished truths, I confidently rely upon your candour. In confirmation of every statement contained in this letter, I have appealed to facts, and hazarded nothing that cannot be sustained by direct consecutive argument. I could not act so insincere a part as to endeavour to impose upon you plausibilities for truths, in order to accomplish an end to which my mind might be directed.

Worthy as you are of a representative incorporation,—capable as you are of endowing it with dignity and credit, it would be a most unwise neglect of an auspicious opportunity to abandon your claims to independence. The profession was never fully aware until this crisis, of its omnipotent influence as a political body,—it never, until these last few years, felt, or expressed, a confident assurance of its claims to scientific distinction:—its members, negligent of their position, widely separated, and disunited, immersed in the routine of their daily avocations, pursuing science by their individual exertions, unencouraged by the patronage of their collegiate institutions,—without much community of sentiment or local intercourse,—accustomed to venerate, with an almost slavish obsequiousness, whatever emanated from their official superiors, or from titled graduates, and often to view with incredulous distrust, the labours of their own class; they were scarcely conscious of their own achievements—of their own capabilities, and of the rapid elevation which their order had undergone in public and scientific opinion. These days are past away,—and for ever! The time has arrived, when your claims must be acknowledged, and enforced, and when, by the establishment of a New College, your superiority may be declared. Is this not an object worth striving for? Is it one that can be suddenly abandoned in the attempt to encompass a chimerical project? Surely not,—and you will not so tamely yield your present commanding position.

I have engaged your time longer than I intended, but the importance of this crisis must be my excuse.

I remain, gentlemen,
Your sincere well-wisher,
GEORGE ROSS.

Kennington, June 10, 1845.

THE MEDICAL TIMES AND MEDICAL REFORM.

To the Editor of the "Medical Times."

SIR,—Yours is the only weekly journal to which the members of the profession have to look, and upon which they can depend, in reference to the Medical Reform Bill at the present time before Parliament. The editor of the *Lancet* is incessantly engaged in a petty squabble with the committee of the National Association, which originated in a paltry pique, and has shewn himself the *greatest enemy of the medical man* at this the most important crisis of his life. The editor of the *Medical Gazette* is pursuing a very "namby pamby" course, and probably thinks that it matters but little to the medical man whether the Bill pass or not; for, certain it is, that not a word was printed in his last number having reference to the subject either one way or the other. *You* have taken upon yourself, sir, the duty of antagonizing the errors of *commission* on the one hand, and those of *omission* on the other; and you are, single-handed, doing your duty most valiantly. I doubt not that you will meet with your reward, and that the members of our peaceful profession will patronize you with gratitude when the day of turmoil shall have passed away, and all shall again be calm and settled.

Thousands admire your advocacy of the proceedings of the committee of the National Association, and of the establishment of a separate College of General Practitioners, and I trust that you will still co-operate with them in getting the Bill of Sir James Graham through the House, which undoubtedly will have a weighty effect in enhancing the interests of the profession.

Two or three *minor points* appear to me to require some modification, and I shall be obliged if you will direct the attention of the Committee of the House of Commons, of the Committee of the National Association, and of the profession generally, to them through the medium of your journal, and I doubt not, if you find that the portions of the clauses to be referred to are likely to *depreciate the present race of General Practitioners*, or to *press too heavily upon the future race*, who, influenced by a very laudable ambition, should wish to possess themselves of the M.D. degree; that you will lend your powerful advocacy to a more liberal construction of such clauses, before the passing of the Bill.

1.—The *Supplemental* Register (clause 33) appears to me to be unnecessary and *invidious*, inasmuch as it will lead to the possibility of misconception on the part of the public as to the nature of the qualification of those registered therein, and of *mis-statement* on the part of those who may desire to make it appear that the "physicians," "surgeons," or "general practitioners," so registered are persons of a *lower grade* in practice than those whose names will be inserted in THE—or the regular orthodox (if the expression may be allowed)—register.

However stringent may be the regulations as to the registration, and the restriction as to the mode of practice, of the *future* members of the profession; it would undoubtedly be a less objectionable plan to have *but one register*, and to allow the *present race* of medical men to register in the three departments, as they may shew themselves gratified by the diplomas they have in their possession.

2.—It will also be invidious to particularize whence the qualifications were derived of those who may register in the supplemental register. The mode of qualification will in future be fixed and uniform, but there should be no mark appended to the names of those who may register with their present qualifications, whereby there could be by any possibility an invidious distinction.

3.—The part of clause 38, which provides that "none but persons registered as physicians shall use the title of doctor," appears to me to be by far too stringent; and I am at a loss to conceive how it can be carried out. It will certainly be a new and odious feature in medical prosecutions to observe, for instance, a well-educated general practitioner brought in guilty of "a misdemeanour in England and Ireland, and in Scotland, of a crime and offence" for using a British M.D. degree, which he may have well earned by a protracted course of study, and after a rigid examination. Unless such degree has been procured by examination from some recognized university, let a person be liable to punishment for passing himself off for what he is not, and such an enactment would be sufficient to put a check to such species of quackery. Surely there can be no *just* law passed to prevent the use of a proper degree by the well-educated possessor of it, although he may be pursuing the humbler sphere of general practice! The law *may be just* in preventing the future *General Practitioner*, in the possession of the M.D. degree, from *registering* as a *Physician*; but I conceive it would be most *unjust* to subject him to the possibility of being found guilty of "misdemeanour," &c., for styling himself doctor, or for using the said degree in any manner he might think fit.

By inserting these few remarks, you will oblige,
Sir, your obedient Servant,
CHIRURGUS.

[Our correspondent is in error, we think, on the use of double titles.—ED.]

WAKLEY v. THE MEDICAL TIMES.
(*From the* Morning Herald.)

It will be in the recollection of our readers that, at the beginning of this term, Mr. Bramwell obtained a rule to show cause why the writ of inquiry in this case should not be executed before one of the judges of this court, instead of before the sheriff of Middlesex, on the ground that the libel complained of affected the plaintiff in his public character as member of parliament for Finsbury, and coroner for Middlesex; that it was his intention to adduce other libels in evidence, published by the defendants against him; and that many important questions of law would be likely to arise in the course of the inquiry.

Mr. Martin and Mr. Parry now showed cause, and read the affidavits of two persons who heard the plaintiff declare that he would ruin the defendants with law expenses, and that he was resolved to destroy their journal (the *Medical Times*); and an affidavit of the defendants' attorney, to the effect that no important questions of law would be likely to arise. They also submitted that the libel complained of did not affect the plaintiff in

his public character, and even if it did, that that was not a sufficient reason for not sending this case, like all others under the same circumstances, to the sheriffs' Court; and that if any important questions of law should arise, it was well known that Mr. Under-Sheriff Burchell was perfectly competent to deal with them; that the defendants had, by suffering judgment to go by default, done all that they possibly could to avoid expense; that a trial before a judge of this court would be four times more expensive than a trial before the sheriff; and that it would be very hard on the defendants, considering the declared views of the plaintiff against them, to expose them to this unnecessary expense.

The Court, without calling on Mr. Bramwell to support the rule, said that the libel affected the plaintiff in his public character, and that they saw no reason, under all the circumstances, why the rule should not be made absolute.

MEDICAL REFORM.

At a meeting of the Defensive Association of Surgeons, held at the Crown and Anchor, on the 31st ult., the following resolutions were unanimously passed:—

Resolved.—That this Association express its strong approval of the alterations introduced in Sir James Graham's measure of Medical Reform, and especially tender to that Right Honourable Gentleman its best thanks, for the concession of a New Royal College, under whose responsible government, the General Practitioners of this country may be shielded from those injustices and insults they have had to bear during their connection with the Royal College of Surgeons.

2. Resolved.—That as the Managing Committee of the National Association of General Practitioners admirably fulfil the duties imposed on them by the circumstances of the Profession at this critical moment of its history—this Association do testify its confidence, in their zeal, wisdom, and good intentions, by recommending all its members to unite with and support that body.

3. Resolved—That while thus identifying itself with the policy of the National Association, this meeting respectfully urges on the Committee of that body the expediency of using their best efforts to establish the franchise given by their New Charter on a wide and comprehensive basis, and to introduce a fair proportion of General Practitioners on the Board of Preliminary Examination.

4. Resolved—That it is most desirable that the Profession should be heard by counsel at the bar of the House of Lords against the Charter recently granted to the Royal College of Surgeons of England, and that every Surgeon be invited to lend his best support to that object.

Signed on behalf of the Committee,
W. Griffith, Chairman.

W. B Costello }
John Foote, } Hon. Secretaries.

To these resolutions, communicated by Mr. Griffith, the following reply has been sent:—

"To William Griffith, Esq., Chairman of the Committee of the Defensive Association of Surgeons, 31, Lower Belgrave Street.

"Sir,—We beg leave to acknowledge the receipt of your favour of the 4th instant, with a copy of the resolutions of the Defensive Association of Surgeons, passed at their meeting of the 31st ult., which have been laid before the Committee, by whom we are requested to assure you how highly they estimate the approval and confidence of the Defensive Association, and to state that the suggestion contained in the resolution will have the best consideration of the Committee.

"We are, Sir,
"Your obedient servants,

JAMES BIRD }
HENRY ANCELL } Hon. Secs., *pro tem.*

The National Association of General Practitioners in Medicine, Surgery, and Midwifery.

* Office, 294, Regent-street, 7th June, 1845.

THE DAILY JOURNALS.

We are glad to see articles in the *Chronicle* of June 9th, and the *Advertiser* of the 10th, on the subject of Medical Reform. We observe that the opinions of both, however much they may be opposed to Sir James Graham on other matters, are still in favour of the fundamental principles of the Bill, and especially advocate the policy of accepting the Incorporation of the General Practitioners. With regard to the Bill, the *Chronicle* remarks, "on the whole it is gratifying to think that the Bill, as at last amended by the Home Secretary, gives us a fair promise that the question of Medical Reform, so long agitated, will be settled this session, and not unsatisfactorily. From the first we have expressed our unwillingness that the government measure should be suffered to fail through an indiscriminate opposition on one side, or ill considered and groundless obstinacy on the other; and we should now be rejoiced to see such a mutual understanding between the contending parties as might prevent parliament rising this year without having disposed of the question finally.** The success of a good parliamentary measure is as desirable to the profession as it is to the home secretary; but there is a price which would outworth the boon to both. It behoves all parties therefore not to higgle and stand out about trifles. Sir James Graham has undoubtedly introduced in his present measure considerable improvements; let him not oppose the one or two others which are still stoutly contended for; and his measure will receive a hearty greeting not less from the profession than from us."

The *Advertiser* in an able article, while speaking of the Association remarks; "if the members of the profession are rationally active as ordinary individuals to their own interest, if they properly feel the wrongs and indignities that have been cast upon them, and if, above all, they are properly possessed with a sense of their responsibility towards the public, they will secure both the New Incorporation and (by its means) a thorough reform of the College—"*a pressure from without*" will effect these objects, and nothing else. They will either gain or lose both."

The advocacy of the amelioration of Medical Government by the Morning Journals, has been a circumstance extremely serviceable to our interests, and we cannot too emphatically tender them our best acknowledgements.

MEETING OF MEMBERS OF THE COLLEGE OF SURGEONS.

(FROM A CORRESPONDENT.)

A meeting of surgeons, called by public advertisement by Mr. Wakley, was held at the Freemasons' Tavern on Saturday evening last, Mr. Bottomley, of Croydon, in the chair, to take into consideration the best means of preventing any so-called "Separation" of Surgeons from the London College. About thirty-five gentlemen assembled, by far the greater number being evidently mere curious spectators of the proceedings. Mr. Ottley was nominated by Mr. Wakley to succeed Mr. Hughes, who resigned, through Mr. Wakley, the post of Honorary Secretary. Mr. Wakley then presented *one* note from a provincial Surgeon (of course a specimen of thousands he is daily receiving), and stated, that he had never known anything approaching to the excitement caused by the Amended Government Medical Bill. The honourable gentleman could use no epithet sufficiently strong to express his condemnation of the measure. It was of great importance to allow the members of the Profession in the country to express their opinions. On a former evening it was agreed, that an aggregate meeting of the Profession should be convened for Tuesday, the 24th of June, and at this, Mr. Guthrie had consented to preside. He (Mr. Wakley) proposed that a public breakfast should be also given on the day before this meeting, in order that those gentlemen who came from the country might have an opportunity of hearing the measures to be proposed previously to their attendance at the aggregate meeting. He hoped some gentleman would propose that a deputation should wait on Mr. Guthrie to request him to preside at the breakfast also. He then proposed Monday, the 23rd of June, at two o'clock, as the day and hour for the breakfast, seconded by Mr. Ion, and carried by a show of six hands. A Mr. Moore, of ——, then proposed (as desired by Mr. Wakley) that a deputation should be sent to request Mr. Guthrie to preside at the breakfast. This was also seconded and carried. Mr. Wakley then proposed that each gentleman present should sign, on a paper sent round, his name and address, and whilst this process was going forward, Mr. Ottley read a letter he had received from Manchester on the College question. Mr. Wakley then said that he had an insuperable objection to large committees, especially when composed of *seventy-two*: he, therefore, begged to propose that the Chairman and two Secretaries be requested to make all arrangements for the public breakfast. This was objected to by the Chairman: his engagements did not allow him to undertake so serious a responsibility. Mr. Ottley also objected on the same grounds. Mr. Wakley said that if aid were required, the honorary officers should themselves select some gentlemen for that purpose. After a desultory conversation, it was agreed to divide the responsibility among five gentlemen, viz.—the three honorary officers, a Mr. Evans, and the before-mentioned Mr. Moore, with power to add another from each metropolitan borough if they can find him. Mr. Wakley then hoped that the Surgeons present would take on themselves to call meetings in the different metropolitan districts, for the purpose of electing representatives to attend the aggregate meeting to be held on the 24th. He proposed that books should be opened in every district, in which those gentlemen who were in favour of the chimerical union of the General Practitioners with the College of Surgeons, might enter their names, and that such as were enrolled, should alone have the right of voting at these meetings, in the election of representatives. This would be very necessary in order to prevent gentlemen opposed to the object in view from voting at the meetings. He also proposed that each representative should contribute £2 towards the defrayment of expenses. A gentleman, whose name we did not hear, objected to the proposition of enrolment, on the ground that the medical men in the districts would not trouble themselves to sign their names. He had himself perambulated with a paper for signature, containing the requisition to Mr. Guthrie, and each name he had obtained (the number collected he forbore to mention), cost him half an hour's persuasion. He was convinced, therefore, that *very few, indeed*, would even cross the street for the sake of enrolment. Dr. Lynch moved as an amendment, that the proposal for calling meetings for the election of representatives should be made at the aggregate assembly on the 24th. To this Mr. Wakley objected that the representatives would be required to attend on that day. Mr. Wakley withdrew his motion, and left it to the committee to decide the question. Dr. Lynch proposed that a circular should be sent to each gentleman who had signed the requisition to Mr. Guthrie, requesting him to obtain signatures in a book, and that, with respect to the country, a circular should be sent to one or two Surgeons in each town, by their means, to be reprinted and distributed among their professional brethren in the neighbourhood. After a long and desultory discussion, this motion was agreed to, and the majority of the meeting having separated, from the lateness of the hour, we left Mr. Wakley and his five or six coadjutors to their futile machinations.

How to Print a Picture from the Print itself.—The page or print is soaked in a solution first of potass, and then of tartaric acid. This produces a perfect diffusion of crystals of bi-tartrate of potass, through the texture of the unprinted part of the paper. As this salt resists oil, the ink-roller may now be passed over the surface, without transfering any of its contents, except to the printed parts.—*Mr. Faraday.*

EFFECT OF THE NEW MEDICAL BILL ON QUACKERY.

Mr. Edward Carter, assistant-overseer and land agent of Ottery St. Mary, Devon, has addressed a petition to the House of Commons, of which the following is an extract:—"Your petitioner has for a long time been in the habit of giving to those who desire it an application for the eye, which has proved beneficial to a great number of persons, some of whom have been unable to find relief elsewhere; your petitioner, therefore, prays that he will not in this land of freedom, be restricted in doing to his neighbours as he would wish to be done unto. Your petitioner further prayeth, that the person appointed to carry into effect the charity given by one Thomas Axe, Esq., to the poor of this parish for drugs and plasters, may be exonerated from any fine or penalty, under any act or acts of Parliament to be passed by your honorable House." Great numbers are in the same situation as the unfortunate Mr. Carter, whose career in medicine, should the Bill pass, is likely, soon to be terminated somewhat abruptly.

FUNERAL OF M. BRESCHET.

The obsequies of this eminent physiologist were performed at the Church of St. Germain-des-Prés, in the midst of a vast concourse of members of all the scientific and medical societies of Paris. The remains were deposited in the Cemetery of Père-La-Chaise, near those of the celebrated Etienne, and many other fellow-academicians. Orations were delivered by MM. Andral, in the name of the Academy of Sciences; Pariset, on behalf of the Academy of Medicine; Cruveilhier, in that of the Faculty of Medicine; and Ferrus, in the name of the friends of the defunct. An *interne* of the Hôtel-Dieu, M. Dumarquais, added some touching words expressive of the deepest regret of the pupils of M. Breschet. This celebrated man was born at Clermont Ferrand in 1783, in the College of which city he commenced his studies, and from which he removed to Paris about the year 1800, for the purpose of entering the Polytechnic School. It would occupy too much of our space to recount the public contests (*concours*) in which he was the successful competitor. To English physiologists, the writings of M. Breschet are as well known as they are by those of his own country; and it would be difficult, indeed, to peruse a paper on any physiological subject, and not find allusion frequently made to them. There is scarcely a subject connected with minute anatomy and physiology to which he did not add some important information. As M. Cruveilhier observed in his oration, "the great number of original treatises which he wrote, attest that he had all the qualities of a good observer, and a great predilection for minute anatomy." His treatises on embryology; his memoirs on the structure of the skin; upon the structure of the organ of hearing in man and animals; upon aneurism; upon the lymphatic vessels; upon bloodletting; and his magnificent work with plates, upon the venous system, a work which, we regret to say, is left by his death, to a certain extent unfinished, bear incontrovertible evidence of the extent of his labours, and furnish an example of what can be achieved in a comparatively short life. But his labours are not comprised in this list, for he contributed a large number of papers on different subjects to the various medical and scientific societies, and was the translator of several German works on transcendental anatomy. Lastly, and what should not be regarded as of little moment, M. Breschet was not respected simply for his scientific attainments: he was also a man in the best sense of the word: he was endowed with all those passions, those feelings which ennoble human nature, and which—in the words of M. Ferrus—enabled him to leave this world with the esteem of all good men.—(*From a Correspondent.*)

Aneurism of the Arch of the Aorta.—Dr. Favell at a meeting of the Sheffield Medical Society, exhibited a fine specimen of aneurism of the arch of the aorta, taken from the body of a man, aged 58 years, by trade a chair-maker. At the time of his admission into the Infirmary, (January 10, 1845,) he stated that he had generally enjoyed very good health, but suffered from an attack of rheumatism, chiefly in the lower extremities, about five years ago, from which he entirely recovered in about three weeks. Six months since he began to be troubled with cough and expectoration, accompanied by difficulty of breathing, and pain in the right side of the chest. For these symptoms he applied for medical assistance at the Dispensary, and after remaining under treatment for between three and four months, was at length discharged cured. Very shortly afterwards he discovered a small tumour, about the size of a marble, on the right side of the chest, which gradually increased in size. At the time of his admission, the tumour was situated half an inch to the right of the sternum, and occupied the space between the second and third ribs. In form it was elliptical, and measured three inches and a half in length and diameter; its elevation above the surrounding integument was one inch, and its superior edge was an inch and half below the inferior margin of the clavicle. The tumour pulsated very strongly, and on applying the stethoscope, a loud churning murmur was heard synchronously with both sounds of the heart. He died on the 7th of February. On examining the body, there was found a large aneurismal sac, involving the whole of the arch of the aorta. The sac was entire and closely adherent to a portion of the right lung laterally, and to the costal pleura anteriorly. The portion which formed the external tumour was lined with several layers of coagulable lymph. The lining membrane of the sac, as well as of the descending portion of the aorta, was entirely destroyed, and large plates of bone, most of them only partially adherent to the sides of the vessel, were deposited in the subserous cellular tissue.

Schirrhous Pylorus: Inflamed Lung: Valvular Disease of the Heart.—At a meeting of the Sheffield Medical Society, Dr. Favell exhibited the preparation of a pancreas, which was attached by a broad band of lymph, about an inch and a half in length, to the inferior margin of the stomach. The pancreas was in a scirrhous state, but the coats of the stomach were healthy. Also a portion of lung intensely injected, and of a very dark colour, the outer surface covered by an abundant deposit of lymph, and the lining membrane of the bronchi much inflamed, and a heart rather larger than natural, having the left auriculo-ventricular opening at least one-third larger than usual, and the mitral valve correspondingly enlarged. These specimens were taken from the body of a man, aged 66, who was admitted into the Infirmary under the care of Dr. Favell, complaining of a sense of heat at the stomach, accompanied by slight pain. The sense of heat was constant, but the pain only occasional; the appetite was good, and the symptoms were not aggravated by taking food, or by pressure on the epigastrium; there was no sickness, and the bowels acted regularly. He was relieved by the trisnitrate of bismuth, with bicarbonate of soda, and became an out-patient, but was re-admitted in the course of two months, with hæmoptysis, under which, it was stated, he had been suffering for several days. When he was seen by Dr. Favell, he complained of severe pain in the right side, which was accompanied by cough and very copious expectoration of blood, which was of a dark black colour, and frothy: there was no admixture of viscid mucus. The chest yielded a tolerably clear resonance on percussion, whilst the stethoscope detected a loud pleuritic frottement over a considerable space of the right side, exactly corresponding to the situation of the false membrane exhibited, as well as very extensive mucous and sibilant rhonchi. The dulness in the præcordial region was more extensive than natural, but there was no abnormal murmur. The pulmonary hæmorrhage had ceased for some days before death, and was apparently very much controlled by free doses of gallic acid.

GOSSIP AND NEWS OF THE WEEK.

The Leeds Practitioners, Mr. Garlick in the chair, and Mr. Bulmer acting as secretary, have memorialized Sir James Graham, expressing a warm general approval of the amended measure. They express an abstract preference of making the College of Surgeons the home of the General Practitioner, but deeming it impracticable under under present circumstances—urge strongly the passing of the measure this session.

Royal College of Surgeons.—Gentlemen admitted members, on Friday, May 30, 1845:—A. J. Tuckey, J. T. Ross, J. Trague, J. M. C. Cornuel, J. Packer, J. P. Mingaye, D. Davies, F. E. Baston, T. C. Jackson, F. J. Hensley, W. Sedgwick, J. Lewis, H. H. Fitzpatrick, G. N. Epps.

Royal College of Surgeons of England.—Gentlemen admitted Members, on Friday, June 6th, 1845:—J. G. Moir, R. Moore, O. Mullett, S. Gibbon, A. P. May, W. Culhane, J. S. Denham, J. R. Hutchinson, T. M'Greal, E. Pearce, W. E. Wright.—Admitted Monday, June 9th:—F. S. Fleck, H. Ward, J. Ward, T. Peck, T. P. Forge, E. T. W. Mandeville, S. Clift.

Dr. Billing has resigned the office of physician to the London Hospital. Dr. Little, the surgeon-physician, who at present holds the office of assistant-physician to the hospital, is a candidate for the appointment thus vacated by Dr. Billing. He will be elected as a matter of course, such being the ordinary rotation of office at our London hospitals, and there will be, equally as a matter of course, a warm contest for the office of assistant-physician. Dr. Herbert Davies has, we understand, already declared himself a candidate.

It is rumoured that Dr. Chambers contemplates resigning the presidency of the Royal Medical and Chirurgical Society, in consequence of his inability to attend and preside at the meetings. He has, we believe, taken the chair only twice since his election in March last. It would be a bold stroke if the general practitioners, Fellows of the Society, were to propose a member of their own body for the presidency. There are, at least, some of them worthy of the honor of presiding over the first medical society of Great Britain and Ireland. We fear, however, that there is not sufficient energy—not sufficient daring among them at present for such a step.

Society of Arts.—On Monday, June 2d, the president, H.R.H. Prince Albert, presented to the respective candidates the rewards adjudged by the Society during the present session. The following gentlemen received medals for inventions of a surgical character:—"F. Tomes, Esq., of 41, Mortimer-street, Cavendish-square, for his patented dental moving machine, or Dentifactor, a gold Isis medal;" a description of the machine appeared in this journal during the past month.—"Mr. C. Jordan, of Manchester, for his illuminating instrument for inspecting concealed parts of the body, the silver Isis medal."—"John Avery, Esq., of Saville-row, for his speculum instrument for inspecting concealed parts of the body, the silver medal."—"Dr. Davis, of Connecticut, for his patented surgical adjuster for reducing dislocations, the gold medal."

The meeting of the British Association, at Cambridge, is likely to prove of considerable interest, from the number of distinguished scientific foreigners expected. Professor Struve, of Dorpat, Professors Dove, Kreil, Kupfer, and others, will be present, for the purpose of taking part in the Magnetic congress. Professor Foggi, of Pisa, Professor Schönlein, of Basle, and Sir Robert Schomburgk, have also expressed their intention of attending the meeting, and it is hoped that M. Quetelet, Professor Agassiz, and others, will be able to appear. The arrangements at Cambridge will admit of a model-room, for the reception of works of art of all kinds,—forming an extremely interesting feature of the meeting. It is greatly to be desired that all who would assist in rendering this as complete as possible, by sending objects of interest for exhibition, would communicate their intentions to the local secretaries as soon as possible.

No. 300 **SUMMARY.** JUNE 21.

COURSE OF LECTURES ON THE THEORY AND PRACTICE OF MEDICINE.

Delivered by C. J. B. WILLIAMS, M.D., F.R.S., Professor of the Practice of Medicine, and of Clinical Medicine at University College.

The definition of insanity is one of the most important points which medical men have to deal with. It has been defined to be a mistaken judgment on things about which most men are agreed, and different from the former judgment in the same person. This definition was founded on a contracted notion of the true nature of the disease; on the physical notion that judgment was the only active power of the mind, a mere representative of the operation of the mind itself, and that, consequently, insanity consisted either of a perversion of this or an application of it to erroneous purposes—purposes which proceeded from some error, or incorrect idea. The chief objection to this is that it is too partial. There are many cases of true insanity that do not necessarily belong to an error of judgment, while the latter includes a great number of persons not properly insane. One of the most remarkable features of insanity is that it is commonly intellectual error, not so much an error of judgment. There is some strong ruling impulse of thought arising from the feelings more than error of judgment itself; this perversion of feelings may be either partial or general; and the mind may partake of this perversion either wholly or partially. We shall follow the definition which Dr. Pritchard has given of this subject in his treatise. He distinguishes three kinds of insanity, as the chief varieties. The first, the moral insanity in which there is a perversion of some natural feelings, either partial or general, without any permanent intellectual disorder; or if there be any disorder of the reasoning powers of the mind it is secondary. Secondly, the intellectual insanity, in which there is an error in the judgment or the perception; and this includes madness with hallucination, false ideas with regard to things real or unreal. Thirdly, in which the whole mind seems to be disordered, with incoherency; the whole powers of the mind being in confusion and out of place, entirely powerless as it were. In addition to these varieties there is fatuity, idiocy, or imbecility, in which there is an absence of power.

Dr. Pritchard defines insanity to be a chronic disease (that is, to be distinguished from delirium) manifested by deviations from the healthy and natural state of the mind, such deviations consisting of morbid reason, feelings, affections, or habits (that is moral), or disturbances of the intellectual faculties under the influence of which the mind becomes susceptible of hallucinations and errors, and persuasions of a particular kind.

Now first with regard to moral insanity. This comes on in different ways; the individual becomes impetuous and peevish, passionate and excited in a great degree, differing in this respect from his usual habit and manners, or else carrying them to a great excess; his conversation is hurried, and where the disease is more partial, the mind is engrossed on some great object, some one or more important projects, of which he is quite full, and there is some absurd notion or impression connected with these on which the mind acts. The ruling passion may be varied in different cases; sometimes opposition, and sometimes over-anxiety about family affairs, and so forth. If this becomes so overpowering, that it engrosses the whole mind, it leads to all sorts of extravagances and absurdities, and when the patient, in giving way to it is resisted, he strenuously asserts that he is right, and shows outrageous madness, and becomes dangerous to society. An impairment of the moral feelings is generally the commencement of insanity, and there is not an error of judgment in the first instance; but the feelings become powerfully exaggerated, and judgment is impaired in consequence. In some cases, the insanity breaks out suddenly, and in others it is more gradually manifested; peevishness of manner, an eccentricity gradually increasing, the temper of the individual becoming more capricious than it ever was before; or sometimes such as it never was before. It is very difficult to trace the first commencement of insanity, to say at what time the mind began to be insane, for in many cases you find eccentricity and oddities about persons which have existed for a long time, and these persons are never considered mad, though they are bordering on madness on certain points. It is a matter of extreme difficulty to decide, sometimes, whether a person is sufficiently mad to render him a subject of restraint, and as a general rule, the proper plan is to examine whether the eccentricity or partial madness is of such a nature as to compromise the safety of the individual and of those around him. In such a case there can be no doubt of the propriety of placing the individual under restraint. This variety of insanity may take place without any marked impairment of the intellectual faculties. It is very apt to come on after some shock to the mind or body; after some heavy affliction, or sometimes after disease, as for example a stroke of palsy or epilepsy, or after fever. It may often be suspected when an individual shows a remarkable change of character, especially in fickleness and capriciousness as to his pursuits, engaging with great earnestness and energy in particular pursuits, or exhibiting great suspicion of temper increasing in a great degree; yet with all these changes and perversions of feeling, the activity of the intellect is still shown by the individual being able to give plausible reasons for all that he does, and all that he thinks; so that if you were to talk to such a person you would suppose he was a very injured man; he talks of the frauds against him, or the ill treatment he has received, or else that he is a very clever man, and he will try to persuade you in a very plausible way, that he is really going to make his fortune. It is often very difficult to distinguish some varieties of insanity from eccentricity, more particularly those in which the tempers of many persons are so wayward that they are apt to give way to bursts of anger and violent impulses, during which they become for a time insane. Of this we have an illustration in a spoilt child, who has been from early life left quite uncontrolled, giving way to every burst of passion, so that it acquires the mastery over his better feelings, and in some sudden fit of frenzy he commits a crime—murder or something of that sort. These persons should be watched with great anxiety for a long time, for this giving way to anger borders on, and ultimately may pass into real and permanent insanity. It is when these gusts of passion and violence of temper shew themselves without provocation, or without adequate provocation, that one would not hesitate to call it madness. Even with regard to moral insanity, the individual may be good and rational on most points, even with regard to his feelings, but there is one particular project on which he is bent, which, if not resisted may end in fatal consequences to himself or others. There are many instances of this kind of insanity, and it is a state in which many persons are led to commit suicide. There are also many instances of madness called melancholy, in which the individual may be able to reason extremely well on all subjects, so that there is scarcely anything to account for the delusion he is labouring under, but at last he becomes depressed to such a degree that his judgment is perverted, he becomes a trouble to himself, and at last commits suicide. There are various other partial forms of insanity, moral insanity as it is called, which consists of exaggerated feelings or impulses, without the mind partaking, in an equal degree, in the disorder. The change is in the conduct of the individual compared with what it was before. Many persons who have been, before, prudent and thoughtful, suddenly become careless, show a great amount of reserve, or talk of private matters in public society. There is a variety of moral insanity that takes place not unfrequently among old people, in which there is a perversion of the natural feelings, or else an exaggeration of them, so that the individual complains of the conduct of all his relations; or else he becomes moved with regard to them in an unnatural way; hence it is a very common thing with regard to old persons to find their moral feelings altered, and even rendered obtuse, and hostile to those formerly dear to them, or sometimes the reverse. There is an exaggeration of affection in wrong directions. It is remarkable in some cases of partial insanity how during some periods, that are a sort of sane intervals, the individuals will be aware of their morbid propensity to murder and to commit suicide, and will tell their attendants not to trust them, as the feeling comes on, sometimes so that they cannot overpower it; they will caution their friends to beware of them. This has several times happened with regard to the commission of murder, and shows the partial character of the feeling, and that it arises from impulse, and not from an error of judgment.

The second variety is intellectual madness, where the intellect and the memory are the seat of the disorder; this being often attended with hallucinations and the belief in unreal events, or with

unreal impressions of events. This likewise may be partial or general. Where it is partial, it consists of an error of either the judgment or conception confined to particular subjects, while the patient may converse well on all other subjects. This constitutes one of the common varieties of monomania. The melancholia of Cullen is a variety of this, though it sometimes includes moral insanity. The case in which Lord Erskine detected the insanity of a man, exhibits in a very strong light how very partial it may be. This man baffled all the attempts of the counsel to elicit from him the slightest proof of insanity, until Lord Erskine, who was made acquainted with his previous history, suddenly put on an air of great reverence, and apologised for having spoken with so little deference to so great a personage, when the man's insanity was immediately revealed, and he declared, "It is true, I am the Christ!" There is another case of a man who had no other kind of insanity than an erroneous notion that he was too large to go through the door. This case was brought to the *argumentum ad hominem*, for some one pushed him through without any difficulty. He fancied that he should be squeezed to death if he went through, and the impression was so strong on his mind, that he actually did die after he was pushed through.

Monomania is connected with moral insanity; the suspicions connected with moral insanity engender hallucinations and feelings under which the individuals labour. Mania or intellectual insanity, is where one impaired faculty has sway over the other powers of the mind, and the general conduct of the individual. General madness often begins at once, without any premonitory attacks; suddenly after excitement of body or mind. After intoxication, or feverishness, the mind often becomes confused whenever it is brought into operation. When the individual talks, or manifests the current of his thoughts, it is all confusion and excitement; at the first outbreak there is a great disposition to talk—he is incoherent, laughing and crying by turns, associated in an extreme degree with symptoms like delirium tremens, and then the symptoms burst forth in all their extravagance. In these cases, sensation is not unfrequently impaired. The third variety is incoherent madness. It begins with excitement like the last: the passions are all bustle and activity, gradually rising up to violence, changing in their character; the body and mind are quite restless; the ideas and motions become more and more rapid, following in quick and confused succession; until at last the individual is wholly engrossed by these internal impulses, and quite regardless of external things. This is the outbreak of the incoherent insanity in which the confusion of the mind is complete, and it does not appear that the patient either thinks, talks, or acts in any reasonable way at all. This form of insanity is sometimes chronic with intervals of rest; the patient often talking nonsense, but in a quieter way. In all cases of insanity the mental faculties appear pretty perfect, but not in madness. Consciousness and perception, generally speaking, are tolerably perfect, but perception is often perverted by hallucinations. A madman sometimes imagines he is the commander of an army, and issues the word of command to his troops to occupy this or that position; while at the same time he is quite alive to the real scenes around him. There is a case of a woman who had a mistaken idea that her husband was dead, and in order to convince her that he was not, her husband was brought before her; in bodily shape she saw him, and acknowledged it, but she said it was the devil in his shape. This may be said with regard to moral and intellectual insanity of the partial kind; the reason and power of judgment are not universally perverted, but there is a great desire to exercise it on morbid riches; a sort of propensity or fondness for morbid and erroneous notions; these notions being strongly implanted in the mind, the mind so far clings to them, that although the judgment will be active and correct with regard to other subjects, it will be duly exercised with regard to these. Great ingenuity of judgment and intellect are often shown by madmen in defending their wrong notions. This is also applicable to the partial variety of intellectual insanity.

The bodily functions are often in many instances much disordered in the different forms of madness. In melancholia, and all those affections connected with great depression of spirits without excitement, the circulation is generally languid; the extremities are cold; the bowels costive; appetite impaired; and there is often loathing of food, and with this there is sometimes connected a desire of the patient to destroy himself by starvation, so that generally in such cases there is considerable emaciation. There is also generally increased vascularity, beating of the carotids and flushing of the face, and sometimes fever. Sometimes, where sleepiness occurs, it is followed by an increase of the symptoms, and if the disease gains ground this is always a bad sign. The exacerbations are accompanied by vascular excitement, and in many cases there is increased pulsation of the carotids and flushing towards the head and face. This is important in a theoretical point of view, because it comes under the head of determination of blood. The bowels are apt to be costive even in the excited form, and subsequently they become loose and dysenteric. Ulcers and fluxes that have been habitual in the individual become diminished. The catamenia of females are apt to become irregular or suppressed, and eruptions of the skin—chronic cutaneous eruptions—disappear. Phthisis, where it exists, is suspended for a time; the exacerbations of insanity return again, shewing in a very marked way the relation which increased vascular action has to the cause and increase of the disease.

With regard to the prognosis of insanity, it may continue only a few days and then cease, and not return again, or it may last for a long period, or for life; varying with the extent of the disease, and its termination may be either recovery, aberration of the mental powers, or fatuity. The proportion of recoveries varies very much in different establishments, and Esquirol calculates that it varies from one in four to one in two. In England the average is below fifty per cent. in public establishments. In the asylum at York, conducted by the Society of Friends, the average of forty-four years has been fifty per cent.; in the Exeter and the Limerick Asylums, the result for thirty-nine years gives the average of recoveries at fifty-two per cent. On the other hand, at Hanwell, about which we hear so much, the recoveries are only twenty-two per cent. for a nine years average; but this being an asylum for the lower classes, many of these cases have been treated in work-houses and infirmaries previously, and they may be considered to be cases of the worst nature. Recovery sometimes takes place suddenly, and in recent cases it is usually after a sound sleep, or after a spontaneous discharge from diarrhœa. More generally the recovery is gradual with lucid intervals. The age of the patient influences the recovery. The young have a better chance, and in old people few above sixty recover at all. Pinel states that the recoveries take place within five or six months, on the average; and Esquirol remarks, that the greatest number of recoveries take place in the first year. The account given by Dr. Thompson with regard to the York Asylum is, that the recoveries take place within three months of the first attack, in above fifty per cent. Esquirol gives a table of cases not complicated with paralysis, in which, out of two thousand and five, six hundred and four recovered in the first year, four hundred and ninety-seven in the second year, eighty-six in the third year, and only forty-one in the seven following years. In a few rare cases, recovery takes place after a much longer period. Pinel gives a case of a girl who was mad ten years, and suddenly came to her senses, on the reappearance of the catamenia which had been suppressed. After the first month the disease is apt to become chronic. Sometimes the recovery is complete, the patient being in mind and body as sound as he ever was; but in the greatest number of cases there is a great liability to relapse, and where the disease is not properly removed, the patients, though quite rational, never have the same strength of mind they had previously.

The second termination is in fatuity, idiocy, or dementia as it is improperly called. Pinel applies that term to incoherent madness, but this is its more usual application; where there is a diminution of the intellectual powers, the individual may be quite inactive and harmless—the physical part of the frame may flourish, while the mind becomes more degraded than ever. However, even then the patient is excited by bursts of mania, and this state is more hopeless than any other, as the individual becomes degraded even below the stupidity of animals, losing not only the intellectual powers, perceptions, and feelings, but the animal instincts. This generally terminates by coma, paralysis, and death.

Madness is not a very fatal disease, the mortality being not above four and a half per cent. In some cases it is more, but it varies very much in different cases, and some mad persons attain a very great age. Many maniacs die from maniacal exhaustion, and many with diseased lungs, or hearts, and from dysentery. Fatuity generally ends in paralysis, which shows itself first in a defective articulation, or general weakness, which obliges the individual to keep a restrained posture, or to lie in bed in the same position, this being followed by sloughing. Eruptions often occur in insane persons. The accidental occurrence of disease is most fatal to insane persons, as it is difficult to distinguish these complications from their not being able to describe their symptoms and feelings.

Of the predisposing causes, hereditary conformation must be considered the chief. It is more common in the higher ranks than the lower; Esquirol considered the proportion to be one half of the higher ranks, and of the lower not more than a third. Probably, intermarriage increases this considerably, and more among the upper classes than the lower. The disease prevails considerably among Jews and Quakers. Hereditary disposition is apt to show itself at the same time of life in different members of some families, just like gout and phthisis, and in these cases it obviously depends on the physical constitution. Esquirol says that convulsions of the mother during pregnancy give a predisposition to madness in the offspring. Fatuity occurs most in children; mania in middle age; melancholy in advancing age, and dementia in old age. The exciting causes of insanity are both physical and moral. The physical causes prevail much among the lower classes, and the moral most among the upper. The physical causes are intoxicating liquors, blows on the head, gastritic, and arteric diseases; disordered bowels; fevers; suppressed eruptions, and metastasis. The moral exciting causes are strong emotions, &c.

COURSE OF LECTURES ON SKIN DISEASES.

By D. J. Corrigan, M.D., Physician to the Whitworth, Hardwick and Richmond Hospital, Lecturer in the Dublin School of Medicine, &c.

We this evening, gentlemen, take up the subject of psoriasis. This is sometimes a disease in which our treatment is not very successful, as do what we will, it will remain some length of time to plague our patient. In these cases, where it attacks the trunk, or extremities, in a subacute form, we may sometimes be successful in removing it in a short time. I do not think that you need ever use blood-letting in this disease. At least, if you do, it should be but very seldom, as I do not think it called for. Here medicine of a purgative class is indispensable, and, I think, that from alkaline purgatives, you will derive more benefit than from any other of the same class of medicine. The use of the warm sea-bath will be of very great service also, and when the disease has become chronic, and will bear stimulation, you will derive additional benefit from the use of what the French term the "alkaline bath." This is nothing more than a solution of carbonate of soda in the water of a warm bath; for this purpose ℥iv carb. sodæ added to the bath, will answer effectually. This makes a bath of sufficient strength, which can, of course, be rendered more stimulating by adding more alkali; it softens the scales, detaches them, and acting upon the exposed skin, excites it to a new and healthic action, and as I have remarked, under its use th

patient often gets well. This disease, in some families, would seem to be hereditary, and we often find it attacking both parents and children; in such instances the use of the warm bath twice or three times a week for some years, or in many instances for the person's lifetime, has prevented the disease from re-appearing. In cases of P. palmaria, which I am inclined to think often depends on derangement of the digestive organs, you will find the liquor potassæ administered in doses of M. xv. three times a day a very useful remedy. Along with this remedy, if the eruption should be in an irritable state, you will receive advantage from the use of ung. cerussæ albæ, and at a latter period you may add to this an equal portion of an ointment composed of carb. sodæ ʒss. ad ung. cetacei ℥j. However, I think that in this variety of the disease, you will derive more benefit from the use of oiled silk as a dressing to the part than from anything else. If you wish to try ointments you can do so, and over these lay the oiled silk dressing; this acts by confining the perspiration of the part, which condensed upon the surface of the silk, keeps the scaly portion constantly moist until it becomes detached, when it acts in a similar manner on the exposed skin, keeping it also moist, and preventing it from becoming fissured again. But in some instances the plans which I have here mentioned fail, and then our treatment must be more or less empirical, that is, we must use remedies which have been found useful in other cases in curing the disease, although we cannot tell why they are so. Among the list of applications which you may have recourse to are, ointment of tar, creosote, ioduret of sulphur, &c. This, I think, is all I have to tell you on the subject of lepra or psoriasis.

We come next to pityriasis, a disease of little or no consequence. This is generally met with in children, and the place it usually attacks is the head. Its attack is most generally as follows:—A child has been some time previously labouring under scarlatina, or some other disease which leaves the skin thin, tender, and irritable; in a few months after, the nurse or mother finds its hair completely white with small scales, which come out in abundance whenever the hair is combed or brushed: this constitutes the disease. In such cases you will find the scales which fall off quickly replaced by a new crop. All you need do here, is to prescribe an ointment or pomatum of ʒss carb. sodæ to an ounce of lard, and let a small portion of this be well rubbed into the scalp every morning and night for a few times, when it disappears altogether. It is, as I have already mentioned, a disease of no importance, but you ought to know there is such a disease. There is a variety of it, which appears on the back of the neck and occiput, and spreads downwards over the shoulders, in which the patches assume an appearance which might lead you at first sight to suppose the eruption one of a venereal character. But if you examine it closely, you will find these patches to want the copper colour which I have spoken of as belonging to the true venereal eruption, and that the scabs are not the result of papulæ, but are merely minute portions of cuticle which are thrown up in the first instance without the intervention of any fluid. These scales present a character which venereal ones do not. You can remove them rapidly by means of friction with the hand or a towel. All you need do is to direct the use of a warm bath once or twice a week for a few times; this will slightly stimulate the surface, and cause it to die away. In many cases of this disease and psoriasis, we find them to come out quite suddenly, and afterwards as suddenly to vanish.

Closely allied in appearance to the discoloration of the skin, induced by this variety of pityriasis, is an affection which I have frequently seen attack the skin of the neck in persons of delicate cutaneous structure. This discoloration appears most generally in females of delicately fair skin and auburn hair. Its first appearance is as a small yellow speck on the neck; this gradually travels over a large extent of surface, until the neck at length presents an appearance exactly like spots, well shown in this drawing. (Here he exhibited a beautiful drawing of an exquisitely beautiful head and face, and a neck which Praxiteles might have taken for a model of beauty and symmetry, but which presented on one side the appearance as if of an enormous freckle.) Now what this proceeds from I do not know; and what is yet more unsatisfactory, I am not able to tell you what will remove it. I have had many cases of it under my care, and although in every instance I tried a multitude of remedies, yet in not a single instance was I successful in curing it. All I can say is, that do what you may, you still will be unsuccessful here, in removing what we must all consider as a very great deformity on a part of the female figure, which is so constantly exposed and open to observation as the neck.

The next disease, icthyosis, is marked by a peculiar scaly or rather horny texture of the cuticle, which becomes altogether changed from its primitive structure. In psoriasis the action would seem to be confined to the skin throwing up patches of cuticle, which scale off and are reproduced, while here it would seem to acquire a power of secreting new matter totally different in structure from its primitive nature. It would seem here to be thrown into a state closely analogous to that of hypertrophy. This is a disease of which I have not seen many examples, but writers in general, agree as to the almost utter impossibility of removing it when once formed. Not having seen as much of this disease as would warrant me in giving you a description of it drawn from actual experience, I shall therefore refer you to works on the subject for information. There is at present a person exhibiting in Dublin affected with this disease. I am sure it must be a good stock-in-trade to her. She presents rather a curious spectacle, and I believe goes under the name of the "Horny Woman." As the disease is worth seeing on account of its variety, and as the price of admission is but one penny, I think you all had better go and see her; and on second consideration, in place of referring you to books, I shall send you to Grafton-street to study icthyosis (shouts of laughter). The next class of Skin Diseases, "Tubercular," contains four orders—*Elephantiasis*, var. A. *Græcorum*, var. B. *Arabum—Molluscum—Morula—Frambœsia.*

A tubercle is a hard, slowly-suppurating tumour, which rises above the level of the skin, and which sometimes secretes on its surface a fluid which forms a scab, while in other cases the tumour remains without any change. Elephantiasis Græcorum, the ancient leprosy, is a disease which I have never seen, and know nothing of but from description. Not wishing to give you a history of it at second hand, I shall refer you to systematic works for information on this head. Of Elephantiasis Arabum, or the Barbadoes leprosy (a disorder said to be endemic in the island whose name it bears, as well as in other West Indian islands), I may just remark *en passant* that it is nothing more than a state of hyperkrinia of the subcutaneous cellular tissue of the lower extremities. It is a disease exclusively confined to the very lowest of the lower orders of society; and one which is perfectly unyielding to any plan of treatment. It may exist with or without ulceration of the leg, the latter being merely an incident, and quite unconnected with the elephantiasis. Beyond the use of compression by bandage, I am not aware that any other plan of treatment yields benefit. This may temporarily check the action which is going on beneath, and arrest the further deposition of the material which causes the growth of the leg. I shall not delay you any longer by dwelling on this subject, which, after all, is perhaps but of secondary importance, being perfectly indomitable by medicine.

The next disease is one to which the name of molluscum has been given. It consists in the presence of tumours of a pendulous character and of a pyriform shape, which hang from the skin by a narrow pedicle. In the centre of each tumour a small orifice is perceptible from which a fluid secretion issues. This secretion I believe to be contagious. The disease would seem to be an enlargement of the sebaceous follicles of the parts it attacks, partaking perhaps somewhat of a specific nature at present unknown to us. The opinion of the disease being confined to the sebaceous follicles is confirmed by the fact, that on squeezing out the contents of these tumours, they present all the characters of the cheesy matter which these follicles usually contain.

It sometimes makes its appearance in young children, but much oftener in old persons of exceedingly filthy, uncleanly habits, persons who never clean their skin from the accumulation of sordes which the condensation of the perspiration upon it must naturally produce. This coat of saline matter and filth of perspiration blocks up completely the mouths of these sebaceous follicles, and the consequence is that they become inflamed; the disease varying according to the constitution of the person attacked. Thus we find the same cause producing rupia in one, impetigo in a second, and molluscum perhaps in a third. Under these circumstances the cyst becomes enlarged, the sebaceous matter is generated in larger quantity, and continues to be secreted until the follicle becomes so much distended as to be materially elongated and attached to the skin by a very slender pedicle. If the skin on which one of these tumours has grown be viewed laterally, the whole will present the appearance of a pear hanging by its stem. These tumours may appear on any part of the body, and are sometimes very thickly scattered, and of a size varying from that of a split pea to a hazel nut. You will sometimes see as many as 100 on a single person. The means of cure which I have found most successful are—stimulating the surface three or four times by the plain warm bath, or by the use of the alkaline bath in cases where the former does not possess sufficient power to excite the surface to increased and more healthy action. To this I have added the internal use of tonics, such as bark, in its simple form of infusion or decoction; or in its more powerful state of alkaloid, quinine, joined to a nutritious and plentiful diet of animal food. Recollect, as I have said before, that you meet this disease more frequently in old persons of filthy, uncleanly habits, and weakened capillary circulation, than in the young, who possess a more vigorous cutaneous action. The general indications of treatment here are to stimulate the surface by simple or alkaline warm baths, and by the use of tonics to promote absorption.

The next disease of this class is morula or "Button Scurvy," one with which the lower orders are intimately acquainted. It is an affection exceedingly prevalent in some parts of the country. The lower orders themselves are intimately acquainted with every thing necessary for its cure. It commences at first with a reddish elevation of the skin, which feels soft to the touch; this, like a phlyzacious pustule, is seated on a hardened base, and surrounded by an inflamed areola. This tumour secretes from its surface a fluid which dries and forms a scab. This tumour continues to increase until it has raised itself considerably above the level of the skin; and in this state presents the appearance of a spherical tubercle, covered with a brownish scab. When pressed upon by the fingers, the feel of fluctuation conveyed is more likely to mislead then than at first. This arises from the looseness and sponginess of texture which the diseased part possesses. These two cases give you a pretty good idea of the form which these tubercles assume, and of the appearance which they present. The only mistake you could make with regard to this would be to confound it with rupia, but a very simple test will always enable you to decide between them. Suppose these two diagrams to represent the two diseases, and you want to know which is one and which is the other;—first put a poultice over each, or better still, a piece of leather spread with lead plaster. Allow this to remain on until the scab comes off; and what do you now find in each? In the diagram which I have supposed to represent rupia, when the scab is removed, you find beneath a jagged, unhealthy ulcer, with everted edges, and sloughy underneath, discharging an unhealthy pus; whereas, when the scab is removed from the other, morula, it still presents a tuberculated appearance. It is now red, soft and pulpy to the touch; elevated above the level of the skin with its surface still secreting a fluid, which, if allowed to dry on it, again forms a scab. This disease is liable to appear on any part of the body, but there are some situations in which

its appearance might lead you to mistake it for other and different diseases. On the scrotum, a situation it frequently attacks, it presents characters which you might mistake for lipoma of the part. The scrotum is covered with roundish elevated patches, closely resembling fungous growths. These patches, owing to the natural rugosity of the scrotum, are deeply fissured, and sometimes bleed, owing to the irritation to which they are in this situation exposed. These tubercles extend from the superior portion of the scrotum in front, to the left of the nates, posteriorly. On the inferior portion of the scrotum, along the perineum, and through the sulcus of the nates, they do not acquire such an elevation, as on other parts of the body, and are always moist. But in these situations they always occupy a much greater length than elsewhere; in fact you will meet with some cases of it in these situations, which, if you did not examine them attentively, would seem to be one immense flattened tubercle. The attrition of the opposite surfaces here prevents their elevation, but promotes their longitudinal extension; and the natural moisture of the parts prevents the formation of a scab in these situations. It also appears on the lips and about the alæ nasi, where by an inexperienced or careless observer it might be mistaken for cancer. No one who has ever seen cancer could for a moment fall into such an error. When morula attacks the lips, it still presents the same tuberculated form as on other parts of the body, but you have not the lancinating pain of cancer. You have not the fetid ichorous discharge which attends cancerous ulceration. You have not the condensation of structure in the neighbourhood of these tumours which accompanies cancerous ulceration; nor have you that destruction of tissue which presents the most appalling feature of cancer. This disease is highly contagious. It generally spreads among the lower orders, to whom it is confined, from the habit which prevails among them of using articles of dress in common. The most severe case I ever saw was in an old man, who in buying a pair of second-hand breeches got more than he had bargained for. He was literally covered with it from head to heel, and quite beside himself with fear of the strange and horrible disorder he had upon him. I am inclined to believe this to be a disease of venereal origin. Although we find it occurring in persons in whom neither papular, pustular, nor scaly syphilis is discernible, yet we find it in conjunction with condylomata, which are undoubtedly venereal. I have told you that the vulgar are intimately acquainted with the proper plan of treatment to be pursued here; and I think *even we* may condescend to borrow a hint or two from their plan of cure. As soon as ever it appears upon them they have recourse to the never-failing remedy, mercury; and the preparation in vogue with them is corrosive sublimate. This they use locally and internally; topically in the form of lotion or ointment, and for internal use dissolved in whiskey. You may apply to the tubercles a caustic lotion of sulph. cupri, or argent. nitras, or, if you will, of the oxymur. hyd., which is as good as any you can use. For internal use, direct the mercurial salt to be taken in the dose of 1-24th or 1-12th of a grain three times a day, until the gums become tender. For the cure of this, you need not salivate your patient. All you need wish to produce is a tenderness and turgidity of the gums without salivation. It is astonishing the effects which mercury produces over this disease. No sooner have the gums become painful and swollen from its use, than you may perceive these tubercles begin to decrease in size, shrivel up, and finally disappear. Keep up this action a short time longer (without salivation), and your patient is permanently cured.

Framboesia or yaws comes next. This is a disease peculiar to the West India Islands. As I cannot describe it from personal observation, and furthermore, as from its non-appearance in these countries, it is not likely to prove an object of much interest to you, I shall say nothing about it.

The only remaining class, after having gone through the others, is maculæ or spots. This includes nævi, with which we have nothing to do, their treatment being reserved for the surgeon. Of ephelis or sun marks I have spoken while on the subject of pityriasis, when I told you that I knew of nothing which could remove the discoloration in question. On the whole, this class does not call upon us for any particular attention. This concludes the subject of skin diseases, at least of that portion of them which it is necessary or essential for you to understand. I have not touched upon syphilitic skin diseases, as I am confident that these have been fully entered into by the Professor of Surgery. As I have spoken of syphilitic diseases, I shall just mention one fact which it may be well for you to bear in mind. If at any time you should meet with a skin disease which you cannot refer to any of the orders here described, if, for instance, you have a papular disease which you cannot refer to lichen or prurigo; a scaly disease which does not correspond with psoriasis, pityriasis, or icthyosis; or a pustular disease which not answer the definition either of the psydracious or phlyzacious pustule, or of porrigo—if, in fact, you have an example of what is called an anomalous skin disease, you may set it down as syphilitic, and treat it accordingly.

Before we part, allow me to say a few words about "lupus." This is a disease usually classed among the cutaneous, but erroneously, as, strictly speaking, it is a disease originating in the subcutaneous cellular tissue, and after some time implicating the skin in its ravages. In strictness of nomenclature, it should be placed among the ulcerations. There is a form of ulceration where the quantity of material deposited by the reparatory vessels exceeds that which is in progress of removal by the absorbents; this is called the filling, or healthy ulcer. There is another form, when this state of things is reversed; where the absorbents take up more than the reparatory vessels lay down; this is the phagedenic, or eating ulcer, and in this class should lupus be placed. The situations generally chosen by lupus for its attack, are the cheeks, alæ nasi, and upper lip. When the cheek is attacked, it gradually extends to the eyelids, which it involves in its ravages. When the alæ nasi suffer, the septum narium is sure to be destroyed, along with its investing soft parts. To a disease closely resembling lupus in many particulars, and formerly mistaken for it, I wish to call your attention for a little time. This disease goes under the name of subcutaneous, or esthiomenic scrofula, and for its cure (as for lupus) arsenic was formerly recommended. This disease appears at the same period of life as the other forms of scrofula, that is from the age of childhood up to the term of manhood, or until the person has attained the age of twenty-five or thirty years. It begins in the shape of a small indolent tumour, which may appear on any part of the body. We find it remaining stationary for some time, then inflaming, bursting, the ulcerative process slowly creeping along from the part which has been first attacked, and which heals as slowly. If it appear on the hip, after some time we find the whole buttock surrounded with a belt of unhealthy ulceration; or if it attack the trunk, it pursues the same course, healing in one situation and extending in another, until the body is surrounded by it. This, if allowed to go on unchecked by medicine, will continue for years before it gets well. It would seem as if this form (esthiomenic) of scrofula possessed the power of exempting its victims from phthisis. I can confidently affirm that in all the cases of it which I have seen (and they have been very numerous), I have never known a single instance where phthisis accompanied it, or where it had set in after the former had been cured, while it is a melancholy fact that a very great proportion of those who are afflicted with white swellings of any of the various joints which are most commonly attacked by scrofula, are labouring either under the co-existence of this mischief with pulmonary phthisis, or eventually die of hectic from diseased lungs. This never occurs, at least in my observation, in subcutaneous scrofula. Iodine is the remedy which has been found most useful here, both taken internally and applied locally. You may stimulate the ulcers either by a solution of iodine, of caustic strength, or with the chloride of zinc. You must also prescribe iodine internally; and for this purpose a combination of iodine with iodide of potassium in decoction of sarsaparilla will answer best.

Under this plan of treatment the ulcerations, before unhealthy, assume a healthy appearance; good pus is secreted, healthy granulations arise, cicatrisation progresses, and in a very short time your patient is perhaps permanently cured.

LECTURES ON THE PHYSIOLOGY AND DISEASES OF THE BRAIN,

By J. Bouillaud, D.M.P., M.,A.M.,

Member of the Chamber of Deputies, Professor of Clinical Medicine at the University of Paris, Knight of the Legion of Honor, Physician to the Hospital de la Charite, &c. &c.

Lecture I.

The cerebro-spinal system is composed of the medulla spinalis, the medulla oblongata, the pons Varolii, the cerebellum, and the cerebrum—these two last themselves consisting of several lobes. It will not be uninteresting, therefore, before studying the diseases to which these organs are subject, to pass rapidly in review their functions, which are as important as they are numerous.

The functions of the medulla spinalis are well known at present, but ancient anatomists assigned to the different parts special functions, of whose nature they were far from having any accurate ideas. Sir Charles Bell was the first who determined by experiments the influence exercised by the anterior and posterior cords, assigning motion to the former, and sensation to the latter; although Alexander Walker announced an opinion diametrically opposite. Dr. Magendie, in an article inserted in the *Journal de Physiologie*, supported the opinions of Sir Charles Bell, though at a later period he seemed to adopt the views of Walker. Numerous experiments have been performed since by several physiologists, on the subject under consideration; but it must be admitted, that it is principally the important researches of Dr. Longet, to whom the physiology of the nervous system owes so much, which have settled the point, by confirming the assertions made by Sir Charles Bell. The problem of the localization of motion and sensation in the anterior and posterior fasciculi of the medulla spinalis is now proved beyond a doubt; but there is another which seems to be likewise solved, and to which the attention of physiologists has of late been particularly directed —viz., whether the medulla spinalis ought, like a large nerve, to be considered as merely a conductor of sensation, or to be regarded at the same time as a conductor and a centre of perception. This question has been decided in favour of the latter opinion. In fact, if the whole of the cerebrum and cerebellum are removed, the medulla spinalis and medulla oblongata alone being left, when any part is pinched, the animal will immediately make a movement, with the intention of withdrawing the part from the cause of irritation. If, on the contrary, the brain is left entire, and the medulla divided transversely in any given part, the organs, which receive their nerves from the portion of the spinal marrow no longer in communication with the brain, may be pinched with impunity, and without the animal being affected, as in the preceding case, although it may make some slight movements, showing that the sensibility is not completely extinct. Finally, when the medulla spinalis is entirely destroyed, the brain remaining in its normal condition, sensation no longer exists, nor has the animal any power of making the least movement in order to withdraw the part from the instrument which wounds it.

What must be concluded from these facts? Evidently, that the medulla spinalis is a true centre of perception; that it really receives the sensation of pain, to a certain extent, without the knowledge of the individual; and that it transmits it to the brain, which appreciates it, the latter alone possessing this faculty. Legallois, Prochaska, Calmeil, Marshall Hall, Muller, and Dr. Longet, are of this opinion, and have enriched science with numerous and irrefragable experiments, proving the reflective power of the medulla spinalis.

Legallois performed a great many experiments tending to demonstrate, that the spinal marrow had a very manifest action on the circulation. Without entering into the details which this

subject requires, I will only state that its influence is not direct nor very considerable—a fact admitted by Legallois and many other physiologists; indeed, it is sufficient to read the description of the experiments performed to be convinced of the truth of this assertion. The close affinity, which exists between the ganglionic and cerebro-spinal nervous system, explains the phenomena on which is founded the admission of a direct general influence of the brain, and a peculiar one of the spinal marrow, on the pulsations of the heart and subsequently on the circulation, which, however, are not subjected to the direct or immediate influence of the medulla spinalis. The same remarks are applicable to the respiration; for I do not coincide entirely in opinion with Sir Charles Bell, with respect to the respiratory or collateral fasciculi of the medulla spinalis. In this important function—this function so eminently vital, *respiration*, not only the mechanical and chemical phenomena, but likewise those which may, in a measure, be denominated moral—that is to say, the need of breathing, the most requisite of all, originate in the medulla oblongata, which, like the medulla spinalis, is a conducting organ. All the portions of the nervous centres may be removed without causing any disturbance in the respiratory functions, whereas the extirpation, or destruction of the medulla oblongata alone, especially of the portion opposite to the eighth pair and the roots of the spinal accessory, puts a stop to the respiration.

The pons Varolii, or mesocephalon, is the central portion of the cerebro-spinal system. Is it not well known that it is traversed by the anterior and posterior corpora pyramidalia; that it contains a notable portion of the cineritious substance, which evidently is a prolongation of that of the medulla oblongata; that it is the end of the middle and upper peduncles of the cerebellum, (processus a cerebello ad testes) and that it is from it that the greater part of the peduncles of the brain originate? Its functions must, therefore, be complicated and highly important; and it is not merely a conductor of the nervous fluid, but a true centre, a focus of innervation. In fact, if we wound the posterior surface of the pons Varolii, the animal is violently convulsed, and sometimes cries from pain, proving that this part presides over sensation. If, on the contrary, the anterior portion, the transverse fibres which constitute the pons Varolii are wounded, phenomena indicating perversion of the movements on the side of the body opposite to that in which the injury is done to the mesocephalon are observed. Dr. Magendie remarked that, after the division of the fibres forming the pons Varolii, the animal experienced a rapid rotary motion, somewhat similar to that produced when the middle crura of the cerebellum were divided, and Dr. Longet observed, that when the corpus annulare was wounded anteriorly, the animal did not appear to suffer pain; but that in some cases convulsions took place in the limbs, a circumstance which he attributed to lesion of the ganglionic trunk of the trigemini.

Independently of these functions, there are others of a higher order; for instance, certain general sensations which are constantly abolished by lesions of the pons Varolii—such as the knowledge of our own existence. Stupor, profound coma, and lethargy are produced by congestions situated at the base of the brain, the corpus annulare being affected, and yet in these cases respiration is generally performed with tolerable regularity. But as soon as the medulla oblongata participates in the disease, respiration becomes slower and slower in proportion to the extent of the lesion, so much so, that in some cases life seems to be extinct.

From the numerous experiments performed, it results that all animals, from whom the brain, with the exception of the pons Varolii is removed, retain their tactile sensations, and are capable of performing certain instinctive movements; but as soon as the medulla oblongata (the organ in which Professor Gerdy places the seat of the will) is taken away, these functions are abolished. In short, in reflecting on the reunion of functions, if it were possible to place the soul in any one part of the nervous centres, evidently it ought to be placed in the pons Varolii.

Deprived of cerebrum and cerebellum, animals perform certain instinctive, regulated, motions, as long as the pons Varolii is intact. Thus the part when pricked is withdrawn—the pigeon puts its head under its wing—besides which the respiration and the circulation continue, and the animal, though mutilated, may still live some time; but as soon as the corpus annulare is removed, these phenomena immediately cease, with the exception of the two last, which continue, though much more feebly.

The functions of the crura cerebelli are distinctly marked; the superior and inferior are in direct relation with the phenomena of sensation, and are not conducting fasciculi; the middle preside over motion. When the two first are wounded, the animals experience very violent convulsive movements, and when the third, a rapid rotary motion on themselves, very different from what they perform when the crura cerebri are injured, for then they run round in a circle.

The simple enumeration of these phenomena is sufficient to explain the functions of the crura; it may, however, be added, that the proof of the fibres crossing each other is constantly observed in the lesions of the medulla oblongata, and of the crura, though the experiments of Dr. Magendie have led this eminent physiologist to form a contrary conclusion.

From the numerous experiments performed by Dr. Flourens, and at a later period by Dr. Longet, as well as from the pathological facts recorded by different authors, it may be asserted that among the corpora quadrigemina, the functions of the *nates* have an influence on the sense of vision. Dr. Magendie at first denied this fact, but subsequently new experiments and some pathological facts led him to the conclusion that such was the case. The functions of the *testes*, in spite of all the researches of these two distinguished physiologists, are yet unknown; it is, however, probable that, like the former, they have peculiar functions, and it is to be hoped that physiologists, with the help of pathology, will at some future day, notwithstanding the difficulties attendant upon the experiments performed on organs so minute, and so deeply situated, be able to discover the parts over which they preside. In the present state of medical knowledge, if we sought to assign to each particular part of the nervous centres, a peculiar species of neurosis, it would be difficult to say which are seated in the corpora quadrigemina. What appears to be the most probable is, that certain affections, yclept nervous, of the sight and movements of the eyes, may perhaps originate in a neurosis of these bodies.

REPORTS ON DISEASES OF FEMALES

By EDWARD RIGBY, M.D.

Fellow of the Royal College of Physicians, Senior Physician to the General Lying-in Hospital, Lecturer on Midwifery at St. Bartholomew's Hospital, Examiner on Midwifery to the University of London, &c.

Inflammation of the Cervix Uteri, complicated with general Constitutional Derangement.

H. H., ætat. 40, mother of four children.

Jan. 4, 1840.—Has been under my care for some time as an out-patient at St. Bartholomew's Hospital, with symptoms of inflammation of the cervix uteri, for which it has been repeatedly leeched. She has suffered much from lancinating pains. At first there was much albuminous and white creamy discharge, which gradually ceased afterwards. These symptoms, as well as her general health, have varied considerably at different times: she has invariably derived benefit from the use of leeches to the cervix, especially when they bled well. The os and cervix uteri have ordinarily been hard, swollen, and very painful; but latterly, on two occasions, the os has been soft and of the natural size, although intensely painful to the touch. She has been also occasionally liable to attacks of congestion of the head; and during the last year a considerable disposition to hæmorrhoids has manifested itself, for which reason, leeches have of late been twice applied to the anus; once especially with great relief. There has also been latterly a good deal of congestion and swelling about the os externum, with irritation and prickling in the vagina. At present she is suffering from much gastro-intestinal derangement, with pain in the region of the liver, which is very torpid.

℞ Hydrarg. chloridi. gr. v. hâc nocte et post tres noctes repetanda.

℞ Aquæ menthæ viridis, Aquæ distill. aa ℥vss. Acidi sulph. dil. M. x. Syrupi rhœados ʒss. Misce, et adde magnesiæ sulph. ʒj. solve ft. haust. ter. die. sumendus.

℞ Extr. conii ʒj. Decoct. papaveris ℥viii. M. ft. lotio in vaginam sæpius injiciendu. Hirudines viii. ano.

11th.—Feels much better. The leeches and calomel have acted well, producing much relief. The darting pains are much less; she has only one or two in the evening. There is no discharge. Tongue and appetite better. Rep. medicam.

18th.—Feels generally ill and feverish, but she has not been troubled either with the darting pains or her other pelvic symptoms. Much headache and bad taste in the mouth. Pergat.

Feb. 1st.—Since last report has taken three or four five-grain doses of calomel with improvement in the local symptoms and general health. No darting pains; but last week she complained of severe pain in the left hypogastrium, for which she was ordered to rub in some antimonial ointment. She is prevented coming to-day by the eruption which it has produced.

8th.—Still much pain in the direction of the left ovary. She has had a return of the darting pains: no leucorrhœal discharge.

Hirudines vi ano. Rep. lotio.

℞ Acidi Nitrici dil. M. xv. ex infus. gentianæ co. bis die.

℞ Ext. hyoscyami gr. v. o. n. Rep. haust. menthæ sulph. o. m.

15th.—The menstrual period has arrived without the catamenia making their appearance. Has had severe darting pains and increased pain of the head for the last two or three days, apparently in consequence. Pain in the ovarian region much relieved.

Repet. Hydr. chloridi gr. v. bis in hebdomada. Omitt. mist. gentianæ. Rep. alia.

22nd.—Much headache, with a full and strong pulse: no darting pains. Rep. hydrarg. chlorid. et alia. V.S. ad. ℥xviii.

May 2nd.—Since last report she has passed two catamenial periods without any appearance. The headache was temporarily relieved by the V. S., and she has had no darting pains since; but the bowels have continued obstinately deranged, and the pulse full and throbbing in spite of brisk laxative medicines, and occasional smart doses of calomel, which on one occasion slightly salivated her. During the last week the catamenia have appeared perfectly regularly and naturally in every respect. No darting pains; no leucorrhœa; says she feels better than she has done for the last two years. Has been taking during the last week the following prescription:

℞. Hydrarg. chloridi. gr. ij., Extr. coloc. co. gr. viii. om. nocte.

℞. Potassæ nitratis gr. x. Mist. amygdal. ℥iss M. ft. haust. ter. die. sumend.

16th.—Bowels confined. Catamenia shortly expected; severe headache; frequent darting pains; throbbing pulse. V. S. ad ℥xii. ℞. Hydrarg. chloridi gr. v. bis in hebdomada.

℞. Aquæ menthæ viridis, aquæ distillatæ aa ʒvss.; acidi sulph. dil. m. x. syrupi rhœados ʒss. Magnes. sulph. ʒii. M. ft. haust. o. m. s. Rep. mistura.

30th.—The head was relieved by the bleeding. Catamenia have not yet appeared. Complains of violent darting pains in the left side of pelvis and small of back. Hirudines xij. ano.

June 13th.—Was unable to come last week, being very unwell from severe darting pains, which have ceased since. No discharge nor turbidity of urine. Evacuations fœtid and clay-coloured. Much hæmorrhoidal congestion.

℞. Hydrarg. c. creta. Pulv. ipecac. co. aa. gr. v. o. n.

Rep. haust. menthæ sulph. c. magnes. sulph. ʒii. o. m.

20th.—Frequent darting pains; urine thick; tongue dry; much headache; bowels confined.

℞. Liq. potassæ m. x. Sp. ætheris nitr. ʒss. Aquæ menth. viridis ℥iss. m. ft. haust. ter die sumend.

℞. Pil. hydrarg. Extr. coloc. co. aa. gr. v. o. n. s.

27th.—Has missed the last two catamenial periods, with increase of the darting pains, feverishness, headache, &c. Urine not so turbid.

℞. Potassæ nitr. gr. x. Sp. ætheris nitr. ʒss. Aq. menth. pip. ℥iss. M ft. haust. ter die sumend.

℞. Hydrarg. c. cretâ, Pulv. ipecac. co. aa gr. v. o. n.

Haust. menthæ sulphuricus c. magnes. sulph. ʒij. o. m. Hirudines vj. ano.

July 4th.—Has been very unwell since last report; frequent darting pains until the early part of the week, since which, the catamenia having appeared, she has become easier. Evacuations very light-coloured; pulse not so strong.

℞. Hydrarg. chloridi gr. v. hac nocte, et post tres noctes repetand.

℞. Haust. sodæ tart. effervesc. bis die.

Rep. haust. menth. sulph. c. magnes. sulph. o. m.

18th.—The darting pains and other symptoms much increased. Pergat hirudines x. ano.

August 1.—Leeches bled profusely with much relief; very few darting pains since, and those slight. Much gastric derangement, and bad taste in her mouth. Expects the catamenia to-morrow.

℞. Bismuthi trisnitr. Extr. hyosc. aa gr. v. o. n.

Rep. haust. sodæ tart.

8th.—Much better both as regards the local symptoms and her general state of health. Tongue furred. Pergat.

22nd.—Catamenia appeared during the last week; she had a few darting pains at the time, but otherwise the period was tolerably healthy. Much fulness and heat of head, with sense of drowsiness and confusion. Treatment omitted to be noted.

September 19.—Since last report she has been actively depleted by bleeding and purging. To-day she has much headache and gastric derangement. Merely a show appeared last week at the catamenial period; it was attended with severe pain, and was like coloured water. Tongue furred; breath and taste in mouth fœtid. Pulse quick and hard.

℞. Tinct. digitalis m. xij. Liq. ammoniæ acet. ℥ss. Aquæ distill. ℥j. M ft. haustus ter die sumendus.

Rep. haust. menthæ sulph. c. magnes. sulph. ℥ij. o. m.

26th.—Feels very unwell; is suffering from severe darting pains. No discharge; expects the catamenia shortly.

Examinatio per vaginam.—Os and cervix uteri somewhat enlarged, and *very* hard. Pergat.

November 21.—The same treatment was continued for some time, and then, as she had rheumatic pains of her limbs, and sparing high-coloured urine, she took the tinct. guaiaci ammoniata twice a-day. Catamenia are now present; some leeches which were applied to the anus last week bled well, but the darting pains are extremely severe. No leucorrhœa.

℞. Liq. potassæ m. x. Tinct. hyoscyami m. xv. Sp. ætheris nitr. ʒss. Aq. menth. pip. ℥iss. ter die.

As soon as the catamenia have ceased, let viii. leeches be applied to the os uteri.

January 9, 1841.—Much better in every respect. Menstruated last week sparingly, but with a great deal of pain. Omitt. medicam.

℞. Decoct. scoparii comp. ℥iss. ter die.

℞. Ext. hyoscyami Ext. gentianæ aa gr. v. o. n.

February 6th.—The catamenia did not appear at the last period; she suffered severely at the time from headache and darting pains; feels much better now. No darting pains; scarcely any pain of limbs; no leucorrhœa; urine clear; bad taste in the mouth; tongue creamy; clean at the edges.

Rep. Decoct. scoparii co., pil. hyoscyami, c. gentiana, et haustus menthæ sulphuricus c. magnes. sulph. (May 16th) omni mane.; sumat pil. hydrarg chloridi comp. gr. v. hac nocte.

March 27th.—Is suffering severely from lancinating pains. Examination with the speculum shows no peculiar change in the shape of the os uteri, but its mucous membrane is studded with little patches of a red colour. Examination with the finger, shows the os uteri to be open, circular, cartilaginous to the feel; the edge irregular, and pressure produces lancinating pain. Pergat.

April 10th.—On returning home after the examination she states that a large quantity of puriform fluid was discharged from the vagina, since which all her symptoms have abated. Pergat.

24th.—Feels remarkably well; no pain. Pergat.

April 20th, 1844.—Has discontinued her attendance for two years. The pains in the pelvis still exist, but are much less severe. They abated considerably six months after she ceased to attend; about which time she began to experience pains of a similarly lancinating character in both eye-balls and orbits. Has occasional flashes of light, objects appearing distorted, and surrounded by a halo; occasional loss of sight; vertigo; pain of forehead and occiput, during which the sight is dim. Three or four months ago, she observed that the right eye was becoming enlarged and prominent; its vision is much more impaired than that of the other. At present there is a decided prominence of the right eye, producing a fixed and vacant stare with it; there is a greenish tinge of the pupil. The left eye appears natural; both pupils act naturally. Catamenia ceased in December last; no leucorrhœa; much hæmorrhoidal congestion.

Hirudines vj. ano. ℞. Pil. hydrarg. Extr. coloc. co. aa gr. v. o. n.

Haustus menthæ sulphuricus c. magnes. sulph. (16th May, 1840) bis die.

27th.—No relief produced. V.S. ad deliquium. Pergat.

May 4th.—Pain of eyes somewhat relieved by the bleeding; blood slightly buffed, but not cupped; evacuations light colored.

Rep. V.S. ad deliquium. Hydrarg. chloridi gr. v. hâc nocte. Rep. alia.

11th.—Evacuations still light coloured; much hæmorrhoidal congestion; pain of head and eyes very severe; pulse weaker.

Rep. pil. hydr. c. Extr. coloc. co. Hirudines vj. ano.

℞. Haust. gentianæ c. senna bis terve die.

18th.—Hæmorrhoidal symptoms relieved by leeches; bowels freely opened; pain of head and eyes still severe; tongue dry and pale; evacuations clay-colored.

Omitt. pilulæ. ℞. Pil. hydrarg. chloridi co. Extr. coloc. co. aa gr. v. o. n.

Rep. haust. gentianæ c. senna. Hirud. viij. temp. dextr.

25th.—Head much better; evacuations improved in color.

Rep. medicam. et hirudines.

June 1.—Much pain of head, with dimness of sight; eyes suffused; pulse hard and vibrating; carotids beating strongly; evacuations clayey; urine turbid.

Hirudines viij. ano. ℞. Hydrarg. chloridi gr. v. h. s. bis in hebdomadâ.

℞. Tinct. digitalis M. xij. ex infus. gentianæ co. ter die. Omitt. alia.

20th.—Symptoms unabated.

℞. Antimonii potass. tart. gr. ¼. ter die ex. aqua.

Rep. hydr. chloridi. Omitt. haust. digitalis c. gentianæ.

July 20th.—No improvement. Pulse hard and throbbing.

V.S. ad ℥xvj. ℞. Hydrarg. chlorid. gr. v. hac nocte. Rep. alia.

27th.—Relieved for a short time by the bleeding; motions as light colored as before; much hæmorrhoidal congestion.

Hirud. viij. ano. ℞. Hydrarg. chloridi gr. iij. alternis noctibus.

℞. Haust. gentianæ c. senna ter die.

August 10th.—Was too ill to attend last week, since which the evacuations have become more healthy; the headache and throbbing of the carotids greatly abated; the eye-sight much improved.

℞. Extracti taraxaci ʒi. bis die ex liquore calcis.

℞. Haust. menthæ sulphuricus c. magnes. sulph. ʒij. o. m.

17th.—Head symptoms much improved; evacuations dark. Pergat.

24th.—Much congestion of head. V.S. ad ℥xvj. Pergat.

Sept. 7th.—Headache greatly relieved for two or three days, but has returned since, more severely than ever. Pulse very hard; evacuations dark; complains of rheumatic pains about her limbs. V.S. ad ℥xviij.

Adde misturæ taraxaci, vini colchici. M. xv. bis die. Rep. haust. menthæ sulphuricus.

14th.—Was rather faint after the bleeding; has still much headache, and congestion of head.

℞. Liq. ammon. acet. ʒss., Vini antimonii pot. tart. ʒss., Aquæ distillatæ ℥j. M. ft. haustus ter die sumendus.

Rep. mist. taraxaci m. et n.

21st.—Complains of lancinating pains in the vagina and uterus two or three times a day; the other symptoms are much the same.

V.S. ad ℥xviij. Rep. mist. taraxaci.

28th.—Head symptoms much the same; darting pains troublesome. On examining with the speculum, the os uteri is found red, studded with red points, like the papillæ of the tongue. It was touched with lunar caustic. Pergat.

Oct. 5th.—Has had no darting pains since last report, but has much headache, and flushing of the face; bowels regular; pulse strong.

℞. Tinct. digitalis M. x. Liq. ammon. acet. ʒij. Aquæ distillatæ. Mist. camphoræ aa ʒvj. M. ft. haustus ter die sumendus.

Rep. haust. menthæ sulphuricus c. magnes. sulph. ʒij. o. m.

20th.—Better in general health; still much pain of head, although on the whole it is less; pulse soft; bowels open; no darting pains. Pergat.

Nov. 16th.—Much better; no headache; motions natural.

Rep. haust. ammon. acet. c. antim. ter die.

23.—Pulse soft and natural; no pain in head; bowels natural.

Adde mist. vini colchici. M. xv.

30th.—Head entirely free from pain; right eye seems to have decreased in size; bowels are easily moved and natural; tongue still dry.

Rep. mist. et haust. menthæ sulphuricus.

℞. Extr. taraxaci ʒij. o. n.

January 4th, 1845.—Much pain of head; evacuations dark; cough, with pain of chest.

℞. Pil. hydrarg., Extr. coloc. co. aa gr. v. o. n.

Rep. mist. ammon. acet. c. antimonio.

25th.—Much better in every respect; tongue dry; evacuations twice a-day, and natural. Pergat.

℞. Sodæ potass. tart. ʒij. o. m. ex aqua.

February 1st.—Going on favourably. Omitt. omnia.

℞. Ext. taraxaci ʒij. m. et n.

℞. Acid. nitrici dil. M. xv. Infus. gentianæ c. Infus. sennæ co. aa ʒvj. M. ft. haust. ter die sumendus.

8th.—Much pain of head; tongue red and dry; bowels not sufficiently open.

℞. Pil. hydrarg. Ext. coloc. co. aa gr. v. o. n.

Rep. haust. ammon. acet. c. antimonio.

15th.—Pain of head much relieved; bowels confined.

Rep. pilulæ. Rep. haust. menthæ sulph. c. magnes. sulph. ℥ij. o. n.

℞. Vin. antim. pot. tart. ʒss. Infus. gentianæ co., Infus. sennæ co. aa ʒvj. ter die.

22nd.—Motions light colored. Omitt. pillulæ.

℞. Hydr. chloridi gr. i., Extr. coloc. co. gr. v. o. n. rep. alia.

April 12th.—Still much congestion of head. Setaceum nuchæ. Pergat.

May 3rd.—Much headache; pulse hard; tongue furred. V.S. ad ℥xviij. Pergat.

17th.—Much better; less pain of head; bowels open; pulse natural.

℞. Pil. hydrarg. chloridi co. Extr. coloc. co. aa gr. v. o. n.

Rep. vinum antimonii ex infus. gentianæ c. senna.

24th.—Seton has been in for five weeks, and is evidently producing much relief. The right eye is distinctly smaller. Pergat.

June 14th.—Head symptoms much improved since the application of the seton; she has little or no pain of head. The sight of the right eye is nearly perfect, but it is still distinctly more prominent than the other; no darting pains; bowels regular. Pergat.

CASES FROM PRIVATE PRACTICE,

By Evan Thomas, Esq.,
Late House-Surgeon to King's College Hospital, Fellow of the Royal Medical and Chirurgical Society of London.

Death from the Abuse of Intoxicating Liquors.

Mr. T., ætat. 26, a civil engineer, of very intemperate habits, but who, notwithstanding, has enjoyed very good health, on the evening on the 27th of March, after an early dinner, drank in the course of a few hours about a pint of strong whiskey, and during the evening he made a bet that he could drink a pint of *raw rum* (sixteen ounces)—one half of which he drank at once, and in three minutes' time the other half. Not long afterwards (five minutes) he was perceived by his companions to be fast asleep, snoring—his mouth open, and saliva flowing from it; he became quite insensible, and fell backwards in his chair; they thought he was quite dead. I saw him in about an hour and a half; his countenance was then ghastly pale, and cold; surface generally cold, breathing stertorous, pulseless, eyes half open, pupils insensible to light, and unequally dilated. I used the stomach pump immediately, finding that he could not swallow) and injected about two pints of warm water; he then vomited a large quantity of straw-coloured fluid, having a strong spirituous odour. I also injected a pint of strong coffee, with some sal volatile: he was placed in a warm bed and well clad, warmth applied to the feet, back, and abdomen; he still continued quite insensible, breathing stertorously; the surface generally became equally warm. The bladder being over distended, a catheter was passed, and three pints of urine, having no odour of liquor, were drawn off. I then left him to the care of his friends, leaving strict injunctions that he should not be left alone. The following day he was quite rational, but remembered nothing of what had passed; he was very feverish, pulse very rapid, and the breathing quick; he complained of great palpitation and pain in the region of the heart, as well as at the pit of the stomach; vomited every thing he took, and complained more or less of all the symptoms mentioned, in spite of the treatment that was adopted, till the 30th, when he died. All the information that I could get was, that he was attacked suddenly with great difficulty of breathing and a rattle in the throat, and died in an hour from the commencement of the attack.

A coroner's inquest was held upon the body under the suspicion that death was caused through my want of skill in applying and using the stomach pump; the clamour was also aggravated by a medical man who had attended him some time before when intoxicated (not when poisoned) when he employed other means to those which I adopted; for this reason a *post mortem* examination was performed, which removed all the assertions and allegations, even from those with whom they originated. The throat, œsophagus, and stomach were free from all marks of mechanical injury; there was a large patch of the mucous membrane of the stomach of a cherry-red colour, the capillaries ramifying on the villi, looking as if they had been injected; the brain and its membranes were healthy; the heart healthy, *i. e.*, its valves; the right lung much gorged—the left lung was so much encroached upon by a large quantity of serum, which had been recently effused into the cavity of the pleura, that in some portions it amounted to red hepatization; liver was in the first stage of cirrhosis; spleen very much gorged; kidneys healthy; intestines more injected than natural.

What was the immediate cause of death? Could it not be the rapid effusion into the chest? The fluid must have been of very recent date, for I had very carefully auscultated the chest on account of the palpitation and pain in the region of the heart and shoulder. Did the alcohol excite the pleurisy? The practice of emptying the stomach of its convents with the pump ought to be abandoned. The presence of the tube itself is invariably sufficient to excite vomiting, the most natural and the safest way; had I done so in this case, and the slightest rent been found in the mucous membrane, there were medical men present at the examination who would not have had the slightest hesitation in asserting that the patient died from my treatment, and that he probably would not have done so under that of another practitioner.

Carcinoma of the Tongue treated successfully by Excision.

Robert Jones, ætat. 46, a farmer's labourer, a native of Wales, where he has always lived, and enjoyed very good health till about ten months ago. He says that about that time he felt something the matter with his tongue, as if he had scalded it by taking some hot fluid. This gradually got worse; the tongue began to swell and to protrude beyond the front teeth, and at last an ulcer formed on its dorsum, which has been getting worse ever since, in spite of every kind of treatment that has been adopted. He has been treated by all the surgeons in this locality who consider his case incurable; says that he has never had syphilis, hæmoptysis, nor any scrofulous affection; has never taken mercury.

I saw him on the 5th of January, 1845. He was then in very poor condition, weak, emaciated, very little appetite, deglutition performed with great difficulty, very low spirited, and scarcely able to walk about. On the back of the tongue there was an ulcer one inch and a half in length, commencing opposite the last molar tooth and extending towards the apex; a probe introduced into the ulcer passed deeply in various directions. The whole of the tongue on the right of the raphe, from the base to the apex, seemed to be implicated; there was also a very peculiar fetid odour from this ulcer, which was very different from that resulting from carious teeth; the submaxillary, sublingual and absorbent glands were free from disease.

I succeeded in persuading the patient to go through a course of sarsaparilla and nitric acid for a month, in order to improve his general health, and ascertain what effect it might have upon the tongue. He took it for that time without any benefit, except a great improvement in his general health; he was in better spirits, and was very anxious to have an operation performed. He had no faith in physic, as he had been taking medicine for six months. Having first ascertained that the chest was free from disease, I removed the diseased portion in this way: his head being supported by an assistant, the part was first grasped with a vulsellum and then, with a strong bistoury, that side of the tongue was excised at one stroke. The bleeding was suppressed with a little difficulty by a few ligatures, and the actual cautery.

May 31. *Remarks.* The case went on so well after the operation, that it is useless to say anything about the subsequent treatment. The wound cicatrised in five weeks, and the patient has continued quite well in every respect ever since. Though he has lost one-half of the tongue, mastication and deglutition are performed without much difficulty; his speech is thick, but not worse than it was before the operation. I have ventured to call the disease *carcinoma*, though the history and symptoms of the disease were certainly not such as are usually found in books upon the subject. My friend, Dr. Thomas Inman, of Liverpool, examined specimens of it under the microscope, and has kindly favoured me with drawings showing the elongated cancerous cells, developed upon the *sarcolemma*, and others within the sheaths of the muscular fibrillæ.

Carcinoma of the Tongue?

Jno. Williams, æt. 27, a ship carpenter, native of Wales, where he has always lived, had enjoyed very good health till last January, when he perceived a small pustule on the right side of the tongue, which rapidly increased to its present extent. Of late he has experienced some difficulty and pain in swallowing: has never had syphilis nor any eruptions about his body, and has never taken mercury.

January 4th.—I saw him for the first time; he was then in very good condition. On examination I found a long narrow ulcer one inch and a half long, having a very hard surface when examined with a probe; on the right tonsil there was another exactly of the same character extending along the soft palate to the *uvula*, which it had nearly destroyed. In every other respect he was in very good health; no enlarged glands under the tongue or inferior maxilla. I proposed an operation to remove the whole of the diseased part at once, to which he readily consented. I removed the diseased tonsil and the uvula at one sweep, the patient sitting on the floor, as in the old fashioned way of drawing teeth from the upper jaw with the key. The affected part of the tongue was next removed, the patient being still in a sitting posture; the bleeding was easily suppressed with the actual cautery, and he was discharged well in a month. I saw no more of him till the latter end of February, when he told me that his tongue was worse than ever; he had been at work in South Wales, and had been under the care of several doctors, and of wild-wort doctors among the rest. He consented at last to undergo a second operation; there was now an ulcer of the same character as the former one, extending from within an inch of the soft palate to the apex of the tongue, penetrating deeply towards its centre, and nearly through the mucous membrane, where it is reflected from its under surface. It was now evident that no operation short of removing the whole of the tongue would be in the least degree successful. It was performed, the man sitting, one assistant supporting the head, with another prepared to make effectual pressure over the lingual arteries in their respective courses over the corner of the hyoid bone. The body of the tongue was first firmly grasped with a vulsellum, and its anterior two-thirds removed at one incision; the vessels were secured without much difficulty. Every thing went on most favourably, and the raw surface healed in six weeks; the man has remained in excellent health ever since.

Remarks.—Was the disease carcinoma? It so much resembled the specimens examined by Dr. Inman, that in my opinion there can be no doubt about the case. I was induced to try excision because it had been so successful in the case, R. J. After trying so many remedies without the least benefit, I prescribed for this patient iodide of potassium and sarsaparilla, with the view of improving his health; he had, however, taken it before he underwent the operation, to no purpose. The peculiar smell mentioned in the other case was also very well marked here, and in both disappeared after the operation. As far as I could learn from his own history, the disease re-appeared in the old cicatrix. I may also add that lunar caustic, arsenic, the actual cautery, besides a host of other empirical remedies, had been tried, but without any advantage.

THE PHENOMENA OF GENERATION.

(To the Editor of the Medical Times.)

Commercial-road, London, June 6, 1845.

Sir,—If the following resumè of a paper read by me before a Medical Society last January, will suit your pages, I shall feel greatly obliged by the insertion of it.

I remain, faithfully yours,
JOHN W. TRIPE.

In the following brief paper it is not intended to consider the phenomena attending Impregnation in all organised beings, but chiefly as it occurs in flowering plants and Mammalia.

To arrive at a just conclusion on any of the organic processes, it is necessary that we examine the function considered, in the vegetable as well as in the animal kingdom, as the laws by which the Universe and its inhabitants are governed, are few, simple, and uniform.

The first step consists in the production of a cell, the formation of which has been thus described by Schleiden. The material from which the cell is formed is a structureless fluid, or soft substance named cytoblastema, in which numerous minute granules are produced. Around one or more of these, a sort of coagulation of the fluid occurs, forming an imperfect layer of substance, which gradually becomes more dense until a thin membrane is formed, which increases more superficially than in thickness, so that after a time a space is left between its inner surface and the

granule. Next, a second membrane forms from the first, and enlarging much faster than the former, separates from it, as a watch glass does from a watch, and then gradually rising leaves a cavity, which becomes filled with fluid. The original granule is called the nucleolus, the second the nucleus or cytoblast, and the third and largest, the primary cell.

In the lowest tribes of plants, the above process occurs, but the whole plant being concerned in the reproductive process, impregnation strictly speaking, does not happen, reproduction being effected by the formation of cells within the cavity of the parent, which bursts after a time, and allows of their escape. In tribes somewhat higher, the cryptogamia, and algæ, the reproductive cells are special (*i. e.* distinct from the rest of the structure) but the process is essentially identical, and in some of the lichens, propagation is effected by means of buds. As we ascend the scale, the reproductive organs become more specialised until we arrive at the lowest tribe of flowering plants, the marsiliaceæ, when the thecæ containing the spires, are enclosed with their ovule in one common envelope, impregnation being effected by direct communication, so that this is the lowest tribe in which we have any process analogous to that which obtains in animals, (as far at least as the two sets of reproductive organs are concerned); below which (tribe) the properties of the two appear combined in one cell, and therefore seem to indicate that only one cell takes any direct part in the formation of the future embryo.

In the exogenous plants the phenomena attending it may be briefly described as follows; the pollen grain produced by the male organ possesses two coats, an outer and inner, the former moderately thick, the latter exceedingly thin. On being brought into contact with the stigma, the outer membrane ruptures, and allows of the protrusion of the inner coat in the form of the tube, which passes along the style to the ovarium, where it enters an opening in the outer membrane of the ovule, which contains granules, and mucilaginous matter. The steps which next occur are much disputed, some asserting that a cell forms in the ovule previously to the pollen tube reaching the ovarium, the germ of the plant being furnished by the ovule, the pollen tube exerting no other than a dynamic influence on it, whereas Schleiden makes a contrary statement which will next be considered. He states that a cellule will develop itself from the nucleus of the ovule previously to fecundation (so far agreeing with the others), forming the sac of the embryo, the contents of which are formative matter for cellular tissue. That the pollen grain is a cell with transparent walls, containing granules of starch; the canal of the style, the placenta, and walls of the ovary are covered with cellular tissue (the conducting tissue), which, at the period of fecundation, exudes a mucilaginous fluid. The pollen falling in the stigma, elongates itself as a tube passing along this membrane to the ovule, enters an aperture in its integuments, and attaining the sac of the embryo, pushes its membrane before itself, apparently penetrating the sac, but, in reality, only thrusting the membrane inwards; next, the part above the membrane, being tightly encircled, drops off, leaving closed the other extremity, which produces the lateral organs and the cotyledons, the female part of the ovum affording the integuments of the grain and the albumen. He, therefore, considers, the germ to be supplied by the anther only. Dr. Carpenter, however, believes the so-called starch granules of the pollen to be analogous to the reproductive granules of the algæ, and to afford the germs of the new being, agreeing, therefore, with Schleiden, that the germ is supplied from the anther, the female merely affording nutriment for it. The corresponding phenomena in mammalia are next to be considered. The ovary is a glandular looking body, usually of an oval shape, composed of dense cellular tissue (the stroma), and a number of very small cells the Graafian vesicles), each of which consists of membranes, a contained fluid, and an ovulum; the latter of which is made up of four parts, viz., the germinal vesicle, a number of granules, the yolk and the yolk bag; the best description of which has been given by Barry. He mentions the earliest stage of the germinal vesicle as consisting of minute cells situated within the stroma, surrounded by a granular envelope, and a few oil globules, the central cell containing fluid, and having at a late period a spot on its wall, at which time a new envelope (the ovisac) is formed outside the former. At this period the ovisacs are very small, in the ox, 1-562nd of an inch, but becoming much larger at the period of heat or puberty, when the oil globules cluster around the germinal vesicle forming the yolk of the egg, and the granules arrange themselves in contact with the ovisac, whilst a membrane forming between the two, constitutes the yolk bag. When ready for impregnation, the granules in the ovulum become developed into cells, the germinal vesicle approaches the surface, and an opening forms in the membranes of the ovum (the ovule of Baer), so that anything which entered from without, must come in contact with the germinal vesicle. The external envelope of the ovulum has received the name of the zona pellucida, from appearing microscopically, as a thick ring, around which some of the granules contained in the ovisac arrange themselves, forming a loose membrane (the tunica granulosa); the interior of the ovisac is lined by another membrane (the membrana granulosa), and between these is situated more or less fluid, which is traversed by four bands (retinacula) which retain the ovule in the centre of the ovisac, and guide it, when nearly mature, to the side of the vesicle nearest the surface of the ovary, by retraction of that band. The vascular tunic covering the ovisac with the two membranes above described, form the Graafian vesicle.

When the animal is in a state fit for procreation, one or more of these vesicles project from the surface of the ovary, but at other periods they are scarcely visible to the unassisted eye.

The use of the ovary appears to be the secretion of an albuminous fluid in the vesicles and the formation of an ovule within, which is one of the agents in reproduction, and being thrown off every twenty-eight days in women, causes the phenomenon called the menstrual flux or catamenia. That the two are coincident, are shewn by the following:—cicatrices have been found in the ovaries of women who have never conceived; bodies called corpora lutea, have been discovered under the same circumstances; by an ovule being found in the Fallopian tubes at the time of menstruation, whilst the ovary of the same side had a ragged bloody opening in it leading into a Graafian vesicle, and this in virgins. The same has been observed by Raciborski in his very extended observations amongst mammalia, his statement being, that an ovule or more always escape from the ovaries of animals during the rutting period, whether access to the male is allowed or not; and the same applies to birds, and many of the lower animals. That it depends on the escape of the ovule, is supported by the fact, that at the rutting time of the female mammal, previously to the passage of ova in birds, and also of the pollen to the nucleus in flowering plants, the membrane lining the generative passages secretes a mucilaginous, or muco-sanguinolent fluid, whether a uterus exists or not.

In mammalia, the mode by which the escape of the ovum is effected, appears to be, by a deposit taking place between the coats of the Graafian vesicle, and pushing it (the ovule) forwards, distending the integuments to such an extent, that on being grasped by the Fallopian tube, they burst and allow of its exit. The Fallopian tubes are two in number, attached by one extremity to the uterus, whilst the other is free, floating in the peritoneal cavity, and having fimbriated extremities by which they are enabled to grasp the ovaries. They have each a narrow canal lined with mucous membrane covered with ciliæ. These terminate in the uterus, which may be considered as a continuation of them, serving as a receptacle for the ovum, having a triangular cavity lined with mucous membrane opening into the vagina beneath.

The seminal fluid of the male contains a number of cells called spermatic animalcules, or spermatozoa, each having a large or rounded end, and a caudal extremity. They are an universal constituent of the spermatic fluid in all animals, being invariably found in it during the whole procreative period. They also have a certain determinate form in different animals, coinciding with those of the same species, but differing from those of others. They are imperfectly formed in hybrids. The size of the spermatozoön has not any stated proportion with that of the animal. They differ considerably in their movements, being generally propelled forwards by lateral motion of the tail, but those of passerine birds usually spin round on their axis, advancing in a manner similar to that of a screw, and those of the Salamanders and Tritons lie curled up, exhibiting a jerking movement. The normal duration of their movements varies exceedingly, being shortest in birds (from twenty to thirty minutes,) whilst in fishes they are longer (several days,) and in them the tail is said to drop off in twenty-four hours. But it is probable that when contained within the living organs, whether male or female, their motion exists for a much longer period, as in the bee, and some other animals, it certainly must continue for a great length of time, as the female has a special organ for retaining the male fluid, and thus fertilising the ova as they pass from her body. With the bee, one congress will suffice for one season, and the impregnation of 20,000 ova.

These animalcules, or cells having been injected into the vagina, pass up into the uterus, thence to the Fallopian tube, and eventually reaching the ovary, pierce the Graafian vesicle in a manner identical with that of the pollen tube in plants.* If therefore the menstrual period was not at hand, the aperture existing in the membranes, the ovule being ready for expulsion, and the Fallopian tube grasping the ovary whilst the spermatozoön was within it, the animalcule could not reach the ovule, but would fall into the peritoneal cavity, or on arriving at the ovary could not impregnate the ovule, unless an opening existed in the integument, or it might cease moving previously to reaching the end of the Fallopian tube. That the above conditions are necessary to allow of impregnation, we have already shewn, and may therefore conclude that an ovule does not escape from the ovary of the human female at any other period except just previously to, or at the same time with the menstrual discharge, and that impregnation cannot occur except the male cell reach the ovary just previously to the exit of the ovule from the Graafian vesicle.

Further, every fact connected with the animal and vegetable kingdoms are in favor of this view, and mammalia are not capable of impregnation, except during the periods of heat or rutting, which return at a more or less certain stated period, which periods are marked by the escape of a cell from the ovary, attended with a greater or less secretion of mucus, or muco-sanguinolent fluid, and in plants by the secretion of a mucilaginous fluid with the formation of a small cell (the nucleus) in the ovule. Fishes have their spawning time, birds the period at which they lay, and at which they do not, the fruitfulness of the ova depending on contact with the male cell, but their expulsion on their formation only, not being in any way connected with their impregnation. This is shewn by most of the fishes, the female of which expel their ova without

* We may cite a further proof, the statement of Dr. Martin Barry and Bischoff, that they have seen a spermatozoon on the ovarium, the former in the rabbit, and the latter in the dog. Dr. Barry also states, that he has seen something very much resembling its large extremity in the cleft of the Graafian vessicle. Also the researches of Racisborski in regard to the corpora lutea, who after examining the ovarie of almost numberless animals, both after and previously to any congress having occurred, concluded that the capus luteum invariably differs in appearance accordingly as impregnation has occurred or not. These researches were made in Birds and Mammalia, and prove that to have enabled this change being effected, the spermatozoon must have reached the ovary previously to the escape of the ovule from the Graafian cell, otherwise the corpora lutea, of the mated animal would not have differed in appearance from that of the virgin.

any congress with the male, fertilisation being effected after their expulsion; and the same will happen in birds when access to the male is prevented, but here the ovum does not become fertilised.

Such then being the method adopted by nature in the other classes of animals, why should we expect the human female to be capable of impregnation, at any other than stated periods. Let us then trace out further analogies with other classes, and see what conclusion will be arrived at. In all the essentials it has been, or will be, shewn that she conforms to generallaws.—The number of the future new beings in plants depends on the number of ovules contained within the ovarium, and their impregnation; in animals the greater number of ova thrown off at one time from the ovarium (cæteris paribus) the greater the number of offspring at the birth; in the uniparous animals, but one ovule is expelled at each period, in the multiparous many. The frequency of conception also closely corresponds with the frequency of menstruation, which is shown by comparing the greater frequency with which both occur in inhabitants of hot, than in those of cold climates.

Let us now cursorily compare the reproductive process in both kingdoms. In the lowest order of animals—the sponge, a number of gemmules or granules are thown off from the parent without any stock of nutriment for their future growth, and in the lowest of plants, the protococus nivialis, by the growth of new germs within the parent, which bursts, and throws off the granules as in the sponge tribe. In the polypes by an increase of part of the animal, like a bud from a plant, and in entozon, the young sprout from the interior of the parent. In the highest orders of animals, the ova correspond with the ova of plants, the germinal vesicle of the former, with the nucleus of the latter. The spermatozoa of the one is the analogue of the pollen of the other; they both consist of a cell containing granules, from which it is most probable the embryo is produced. The form of the pollen with its tube whilst passing down the style resembles closely that of the spermatic body, having an enlarged extremity with an elongated tube, so that in form it assumes temporarily, and while at its highest development, that of the permanent condition of the spermatozoon. The form of the spermatozoon, and probably of the pollen, being determinate in each kind of animal, prevents the female, with but few exceptions, being impregnated by the male of any species except her own.

The conclusions then, may be briefly stated. We have shown, that throughout all animated nature, the new being derives its origin from one cell which is the production of the whole plant or animal, in the lowest tribe of each kingdom, and of the male in the higher, the female affording merely the nutriment for it; that with but few exceptions the male cell cannot produce an embryo, unless it meet with an ovule from the female of the same species. The constitution of the cell afforded by the male, and of the ovule formed by the female, are essentially similar in animals and vegetables, and lastly, that the female does not afford ova to allow of impregnation at any other than a certain stated period, which is called heat or rutting in most animals, but in human females is characterized the catamenial discharge.

PROGRESS OF FRENCH SCIENCE.

FROM OUR OWN CORRESPONDENT.

Paris, May 30, 1845.

Academy of Sciences. Sitting of the 29th May. M. Elie de Beaumont in the chair.—Received :—Cambridge Mathematical Journal, Nos. 1 to 9, from Nov., 1837 to May, 1840. Letter of thanks from the Secretary of the Royal Society, London, for the *Comptes Rendus*, sent to the Society by the Academy.

On Chlorurretted and Bromuretted Organic Bases. By M. A. Laurent.—When chlorine is made to act on a hot concentrated solution of hydrobichlorate of cinchonine, a nearly insoluble salt is precipitated, which, when re-dissolved in water, and treated by ammonia, furnishes a precipitate which is a new organic base (*chlorurretted cinchonine*); formula $C^{76}\ H^{40}\ Cl^4\ Az^4\ O^2$. It is cinchonine in which four atoms of hydrogen are replaced by four atoms of chlorine; it crystallizes in needles, restores the blue colour to the tincture of litmus; forms with acids crystallizable salts; and with potass quinoleine. *Bromuretted cinchonine;* by adding bromine to a solution of hydro-bichlorate of cinchonine, a salt is obtained, which, decomposed by ammonia, furnishes a precipitate; formula $C^{76}\ H^{42}\ Br^2\ Az^4\ O^2$; is cinchonine in which two atoms of hydrogen are replaced by two of bromine. *Cinchonine 3-2 bromuretted* is prepared like the preceding, with which it is united, but may be separated on account of its greater solubility; formula $C^{76}\ H^{41}\ Br^3\ Az^4\ O^2$. *Chloroplatinic salts of cinchonine* are distinguished by the quantity of acid and bi-chloruret of platina which they contain, and because they absorb two equivalents of water, which are disengaged at about 266° F. are all of a pale yellow, and nearly insoluble; formulas :—

Bichloroplatinate of Cinchonine.

$C^{76}\ H^{44}\ Az^4\ O^2 + 2\,(H^2\ Cl^2 + Cl^4\ Pl) + 2\ Aq.$

Bichloroplatinate of Cinchonine Monobromuretted.

$C^{76}\ H^{42}\ Br^2\ Az^4\ O^2 + 2\,(H^2\ Cl^2 + Cl^4\ Pl) + 2\ Aq.$

Bichloroplatinate of Cinchonine 3-2nds bromuretted.

$C^{76}\ H^{41}\ Br^3\ Az^4\ O^2 + 2\,(H^2\ Cl^2 + Cl^4\ Pl) + 2\ Aq.$

Bichloroplatinate of Cinchonine bichloruretted.

$C^{76}\ H^{40}\ Cl^4\ Az^4\ O^2 + 2\,(H^2\ Cl^2 + Cl^4\ Pl) + 2\ Aq.$

The hydro-bichlorates and hydro-bibromates are all very similar, isomorphous and crystallize in the same manner; formulas :—

Hydro-bichlorate of Cinchonine.

$C^{76}\ H^{44}\ Az^4\ O^2 + H^4\ Cl^4$

Hydro-bichlorate of Cinchonine mono-bromuretted.

$C^{76}\ H^{42}\ Br^2\ Az^4\ O^2 + H^4\ Cl^4$

Hydro-bichlorate of Cinchonine 3-2nds bromuretted.

$C^{76}\ H^{41}\ Br^3\ Az^4\ O^2 + H^4\ Cl^4$

Hydro-bichlorobromate of Cinchonine 3-2nds bromuretted.

$C^{76}\ H^{41}\ Br^3\ Az^4\ O^2 + H^4\ (Cl^2\ Br^2)$

Hydro-bichlorate of Cinchonine bichloruretted.

$C^{76}\ H^{40}\ Cl^4\ Az^4\ O^2 + H^4\ Cl^4$

Hydro-bibromate of Cinchonine bichloruretted.

$C^{76}\ H^{40}\ Cl^4\ Az^4\ O^2 + H^4\ Br^4$

The author terminates by stating, that some time ago he described, under the name of *isomeromorphism*, a curious case of *isomeric* or *isomorphism*, produced in the same substance first by chlorine and bromine, and afterwards bromine and chlorine; and that he does not doubt the possibility of its being obtained with cinchonine, though as yet he has not attempted it.

On Sulphurous Ether. By MM. Ebelmen and Bouquet.—When anhydrous alcohol is poured on proto-chloruret of sulphur, heat is disengaged and sulphur precipitated; fresh alcohol must then be added until no re-action takes place; when this mixture is distilled at about 176°, alcohol, acidulated with hydro-chloric acid, passes over; by continuing the distillation the sulphur is melted, the liquid becomes of a reddish-brown colour, between 302° and 338°, furnishes a liquid which must be collected separately, melted sulphur remaining in the retort. The liquid obtained between 302° and 338°, rectified until the boiling point becomes fixed, is limpid; colourless; has a peculiar ethereal smell, somewhat similar to that of mint; taste cooling, at first pungent, afterwards sulphurous, boils at 320°; density at 61°, 1·085 : soluble in alcohol and ether; decomposed by water, the precipitate being re-dissolved very slowly and disengaging a strong smell of sulphurous acid; when kept some time in badly stoppered bottles, it is decomposed as by water; formula $So^2\ C^4\ H^5\ O$; it absorbs a great quantity of chlorine under the influence of the solar rays.

Theory of the Formation and Composition of Pyrogenic Substances. By G. Chancel.—The facts examined in this memoir refer to acetone, and to the series of compounds which arise from the dry distillation of monobasic substances, analogous to acetic acid. The general formulas deduced therefrom, explain the production of pyrogenic compounds, the character of the dry distillation, the peculiar affinities presented by particular cases, and the rules concerning acetone; they assign to these substances a general form; define their chemical nature; show that they ought to be considered as simple, but assimilated to compound bodies; for instance, to ethers; finally, they show that they belong constantly to the series of acids whence they proceed; and point out the ties which unite them to the acids, and also the places they occupy in the series.

On the Electro-magnetic Chronoscope.—Professor Dumas read a paper in the name of C. Wheatstone, Esq., F.R.S., corresponding member of the Academy (Section of physique generale), present at the sitting, in which it is stated, that the opinion announced in the memoir of M. Brequet, presented at the sitting of the 20th January last, attributing to M. Konstantinoff and himself the invention of a chronoscope to calculate the rapidity of projectiles, is erroneous, as he had made one many years before. Proofs were given of the accuracy of this assertion.

On the Quantity of Caloric disengaged during Chemical Combinations. By MM. P. A. Favor and J. Silbermann.—According to these authors the numbers representing the quantity of caloric during the combustion of oxide of carbon were : 1° 2388·8 ; 2° 2416·6 ; average 2402.7. During the combustion of charcoal :—

	Not Corrected.	*Corrected.*
First Experiment	7775	8085·0
Second „	7868	8048·7
Third „	7885	8122.8
Fourth „	7861	8086·1
Fifth „	7809	8092·2
Average	7833	8086·02

during the combustion of charcoal with oxyde of carbon 2480·62.

On Electro-Chemistry.—From the facts contained in the memoir, the learned academician considers himself authorised to conclude, that the elements separated by the action of the pile do not move in the liquid with equal facility, for instance, chlorine moves with greater rapidity than gold, and it is on this account that the positive pole is without action on the gold which it has separated from its equivalent of chlorine, and which consequently reaches the negative pole with difficulty, where it ought to be deposited and deprived of the electricity it contains. If this explanation be admitted, there remains to be examined how far this aptitude of moving more or less freely presents an affinity with the volume or mass of the chemical equivalent of the element. That if it be correct that in compound bodies the neutralization of the opposite electric fluids is incomplete, evidently they excite an equal action—that in plunging in a solution, a conductor not electrified, the molecules in contact with the liquid, present the positive or negative power, according to the electric power which predominates in the compound body.

Academy of Medicine. Sitting of the 27th May, M. Caventou in the chair.—Professor Blandin presented two memoirs, one for Dr. Sene on uterine hemorrhage, and the means by which it may be prevented; another for Dr. Corbin, surgeon to the Hotel Dieu, Orleans, on a new mode of extracting foreign bodies from the respiratory tubes.

M. Bouley read several memoirs on mineral waters. As usual when such reports are read, the inattention and conversation of the learned members prevented a word being heard; the conclusions, however, were unanimously adopted. M. Chevalier remarked, that some mineral waters which contain very few salts are, notwithstanding, curative; it may therefore be concluded, that they contain an active principle which has hitherto evaded our modes of investigation, but which probably will, as our instruments become more and more perfect, be discovered.

Professor Velpeau presented a memoir on dropsy in the name of Dr. Desjardins, of Havre.

Professor Berard, in reply to M. Bussy, relative to the nature of the colours employed by M.M. Cartaux and Chailloux, stated that they were those in ordinary use. The conclusions of the report having next been read were adopted.

On Hare-lip. By Professor P. Dubois.—In this communication it is my intention to draw the at-

tention of the Academy to a question still enveloped in doubt, and on which I hope to throw some light; I mean congenital hare-lip, and the age at which the operation ought to be performed. The reflexions here presented are founded on facts observed by myself, and therefore must be rapidly and briefly indicated, and I trust that the objections made by a great number of eminent surgeons, will be successfully combated by the recital of these facts, and by the examination of three children now present. (1)—*Case* 1. About four years ago, a colleague requested me to examine his child, affected with labium leporinum; he wished the operation to be performed immediately, but I reminded him that such was not the opinion of my father, whose pupil he had been, however, as he insisted, and as I was prevented operating on account of a phlegmon of the arm, Dr. Jobert de Lamballe was called in and performed the operation with his usual skill. The child took the breast immediately after, and cicatrization was complete in a few days; unfortunately six months after, the infant died of a disease quite different from that under consideration. *Case* 2.—A few months after I was called in by a *sage femme*, pupil of the *Maternite*, to see a child just born with a hare-lip; emboldened by the success of the preceding case, I operated the next day; a cure was effected, but the child, brought up by hand, died for want of proper care. *Case* 3.—A month after I operated on a child born the day before; the hare-lip was on the left side; the cure was immediate and complete. *Case* 4.—On the 8th of last April, one of my patients was delivered of a child affected with a hare-lip on the left side; the operation performed the next day succeeded. *Case* 5.—A fortnight after, Dr. Sestier requested me to examine a child born about the same time as the preceding, affected with hare lip on the left side, complicated with fissure of the velum palati and the bones of the palate; operation performed immediately with success. *Case* 6.—A short time ago a child was born in the Lying-in-Hospital with hare-lip on the left side, complicated with fissure of the velum palati alone; I operated on it successfully five days after birth. *Case* 7.—Finally, Dr. Depaul, my former *Chef de Clinique*, has performed it with a similar result.

From these facts it may be concluded that hare-lip may be operated on with success in very young infants, and that the facts recorded are too numerous to be considered as exceptions. As to the *modus operandi*, after cutting off the edges of the division, they were united by means of the pins employed by naturalists, and the twisted suture (the pins are scarcely strong enough); no bandage was applied because it is easily put out of order, nor did I have recourse to the hands of an assistant on each side, as recommended by Dr. Bonfils, of Nancy; the pain was acute, but soon over and forgotten; the dressing was so simple that often it was done without waking the child. Professor A. Berard: Might I ask Professor Dubois what is meant by dressing? Professor Dubois: I mean changing the threads, which was performed twenty or twenty-four hours after the operation; the pins were removed on the third or fourth day on account of there being no bandage; in none of these infants did the pins divide the tissues, for though it is true that they are softer, still their vascularity being greater renders them capable of resisting effectually: very little blood, except in one case, was lost; in two it was swallowed and vomited up again in one, whilst in the other it passed in the stools, without giving rise to any accident. The breast was given immediately after the operation; this is important, since it forms one of the counter-indications to its immediate performance, and it was on this account that when operated on at a very early age, the infants were made to fast; now I consider the unsuccessful results might rather be attributed to this abstinence, than to the operation itself. As to my patients, two were fed by hand, the others suckled, and that immediately after the operation, except in one case, in which a few hours intervened. Another objection is the screams to which the operation gives rise, but, in general, children do not cry much, and even when they do, if the pins have been properly placed they will not be put out of place; I had a proof of this in one of my little patients, who screamed so much that I regretted having performed the operation; but the cicatrization was more perfect than in the others. But it may be said, nothing is gained in operating so young, since it is as successful at a later period, but is it not natural to suppose that the earlier it is performed, the less the cicatrix will be visible? A distinction ought here to be made as to the necessity of operating, for instance, if the child is sickly and affected with hare-lip complicated with division of the bones, it ought not to be performed, but only in strong and healthy children, and when the division affects only the lips. As to the consecutive accidents they were very slight, and sometimes absent altogether. A curious coincidence here exists, which is deserving of being recorded, viz.:—that during the month of May, not only numerous cases of hare-lip were observed, but likewise several other deformities of the extremities. From what precedes it may be concluded, 1° that the operation may be successfully performed in very young children; 2° that it gives rise to no accidents; 3° that the objections made against it are not sufficient to cause it to be rejected; 4° and that the opinions generally ought to be modified, if not abandoned. This memoir was received with marks of satisfaction by the whole assembly. *Dr. Husson*,—I thought I heard Professor Dubois explain why the left side is more frequently affected than the right. *Professor Dubois* in reply, said, that he had stated nothing of the kind, besides which, he could give no plausible cause of this extraordinary circumstance. *Professor Roux*, after thanking Professor Dubois for his interesting communication, said that he considered it would be unfortunate, if, on the authority of Prof. D's name, it was concluded that the operation ought to be performed early in every case. The facts recorded are relative to simple uncomplicated harelip, and in this respect, he, (Prof. R.) coincided in a great measure with Prof. D., although he is always fearful of dangerous results, consecutive to operations in very young children, the more so as he has witnessed several which terminated fatally. There is, however considerable advantage in operating when there is a fissure of the roof of the mouth, because the soft parts being united, the anterior portion of the bony palate is closed, leaving only the posterior, which would require, at a later period, the operation of staphyloraphy. As to the cause of the frequency of the disease on the left side, Professor Roux attributed it to the inequality of the primordial forces distributed to the left side of the body. *Professor Dubois* in reply said he thought the operation ought never to be performed when complications exist; that the junction of the lips of the wound is sufficient to stop the hæmorrhage; that it is on this account that the suture is drawn somewhat more tightly at first; and that he does not consider it necessary to detach the upper part of the solution of continuity from the maxillary bone.

Paris, June 5, 1845.

On Diseases of the Eye. By Professor Velpeau.—In my last lecture I mentioned that it was my intention to describe specific iritis, but on reflection I considered it more advisable first to conclude the description of the acute form.

Prognosis.—Iritis is always a serious affection, especially if allowed to proceed unchecked, a fact the more worthy of attention, as several inflammations of the eye disappear even when no remedial measures are had recourse to. Iritis on the contrary if neglected, produces various lesions, such as diminution in size, or immobility of the pupil, opacity of the different media, causing more or less defect, or even loss of vision. Fortunately the danger attendant on this affection is only local, destroying the functions of the organ, but in no respect placing the life of the patient in danger.

Duration.—In general, iritis, when abandoned to itself, lasts some time, seldom less than a month, and even when properly treated does not soon yield.

Treatment. 1° *External Remedies.*—In the treatment of this affection energetic measures must be employed, and in this respect numerous substances have been praised, but as this phlegmasia has not been accurately distinguished from the other inflammations of the eye, and mistakes have frequently been made as to the supposed specific causes which produce it, it was natural that substances should be recommended which have but little or no effect on the disease. In the first place, collyria, ointments, and other remedies, which have a local action, are of no great use unless there be a complication, such as, an injected state of the organ, a slight conjunctivitis, in which case, collyria containing sulphas zinci, or nitras argenti may be beneficial. But on the contrary collyria containing opium, belladonna, hyoscyamus, and the ung. hydrargyri cum belladonnâ, vel opio, in short all those substances which act on the part after having been absorbed into the system are useful. The reasons of the inutility of the former and the efficacy of the latter may be easily conceived, when we reflect that the iris is so situated, that it is impossible for any topical remedy to be applied immediately to it, and that consequently it is only after absorption that any benefit can be obtained. Revulsives ought likewise never to be neglected, blisters, plasters to which tartar emetic has been added, setons and issues may be employed with advantage, inasmuch as they diminish the vascular and nervous action, and induce an advantageous revulsion. A choice, however, may here be made; thus blisters or plasters on the forehead or temples ought to be preferred to setons and issues, because their action is more rapid, and though I am far from wishing to throw any discredit on the two latter, still I say the preference ought to be given to the former as counter-irritants.

2° *Internal Remedies.*—However useful and efficacious the means just described may be, still they are far from being sufficiently energetic to combat acute iritis; it is therefore absolutely necessary to have recourse to internal remedies, which may be comprized under two heads, (*a*) *antiphlogistics.* If the patient be strong and robust, one, two, three, four, and even five venesections may be practised; should he be too weak to support such active measures, local bleeding by means of leeches, behind the ears, or on the temples, and cupping on the nucha, must be had recourse to, and repeated as often as necessary.—(*b*) *Mercury*; when the individual is of a deteriorated constitution, and so weak as to counter-indicate the preceding remedies, calomel must be administered in divided doses. This substance has long been employed in iritis, but with a very different intent; thus it was formerly and is often still, prescribed as a purgative, but an experience of fifteen years has convinced me that its curative effects are but slight when it purges; nay more, if given in such a way as to avoid producing salivation, the results are far from satisfactory; on the contrary its efficacy is indubitable as soon as its action on the buccal mucous membrane is manifest. Clinical facts daily show the correctness of this assertion, and prove that a patient may take calomel for four, five, or even six days, without deriving any benefit, and without any modification being produced in the disease; but let salivation ensue, and immediately an evident improvement is the consequence. It is for this reason that in iritis the patient must be salivated as rapidly as possible, and therefore calomel must be given from the very outset, conjointly with antiphlogistic remedies. Were it requisite to choose between the two, I should give the preference to calomel, because having tried them separately, though I found blood-letting frequently useful, still it sometimes failed, whereas calomel given alone for four or five days, so as to produce salivation, was constantly followed by a marked improvement. There is, however, a disadvantage attendant upon the administration of this remedy, for instance, it may be given for upwards of a fortnight without affecting the mouth. As may be supposed, the practitioner fails in attaining his end in persons refractory to the influence of the remedy, since the disease continues to make progress as if nothing had been done. It is in order to prevent this from occurring, that I combine antiphlogistics with mercurials, because I have re-

(1) These three children were examined by me. In one the operation was too recent to present any definite result; in the other two the cicatrices were perfect and hardly perceptible.—[G. de B.]

marked that the loss of blood induces salivation more rapidly, and even when it cannot be effected (and no sign exists by which this peculiarity can be recognised), we have the beneficial results which generally follow an active antiphlogistic treatment. Again, some individuals bear salivation with great difficulty, and in private practice if we happen to mention the probable result of the medicines about to be employed, we are almost certain to meet with obstacles, arising from the patient's refusal, which are often insurmountable. If through an error of diagnosis or any other circumstance, the disease has on a previous occasion been cured, no reasons, however plausible they may be, will succeed in convincing the patient that this remedy is the most efficacious; besides which, few individuals are aware how dangerous this disease is, and consequently they refuse to take mercury; nay more, many practitioners are themselves averse to prescribing it. But, notwithstanding, and even in spite of these reasons, I affirm, that there is no better remedy in iritis than calomel, employed in the manner I have recommended. But has salivation really all the disadvantages attributed to it? If so, they are excessively rare, when properly and prudently used; for during the last fifteen years I have induced it hundreds of times, and in no one case has it been followed by any serious effects. The looseness of the teeth and necrosis, of which so much has been said, may take place; indeed, I have observed these effects, but they are very uncommon if proper care be taken. Thus to avoid all mischief, as soon as salivation ensues, calomel must no longer be administered, and other measures must be had recourse to; for instance, when the salivary flux is slight, a gargle containing a small quantity of alum, should be prescribed; and when it is more severe, the parts should be rubbed with powdered alum twice, thrice, or four or five times a-day. These means generally suffice to cause it to disappear in the course of a few days. To resume, in the treatment of uncomplicated acute iritis, the following remedies must be had recourse to—1° General or local blood-letting, repeated more or less frequently, according to the patient's strength. 2° Calomel in vi, viii, x, or xii grain doses, combined with opium, so as to render its action on the intestinal canal less powerful. 3° Blisters and other derivations, and 4° gargles, containing alum and powdered alum, when salivation has been produced.

In my next, I shall pass in review the other remedial measures, and then commence with specific iritis.

Remarkable Case of Pleuritic Effusion. — A man entered the wards of Professor Cruveilhier, at La Charite, on account of an affection of the chest which terminated fatally. At the *post mortem* examination, the left side of the thorax was found to be divided into two cavities, the upper one containing serosity in the midst of which was the lung; the lower one, the upper wall of which was formed by the base of the lung, was full of pus. Right lung œdematous. Had paracentesis been performed in this case, the same result would have been obtained as in one already observed by the distinguished professor, where, in a child, the upper part of the thorax was found to give a dull sound after the operation, which led to the conclusion that two cavities existed, and the autopsy proved the correctness of the diagnosis.—*Gazette des Hopitaux.*

GARLAND DE BEAUMONT, D.M.P., B.L., & S., &c.
Honorary Physician to the Spanish Embassy.

PROGRESS OF GERMAN MEDICAL SCIENCE.

By SIGISMUND SUTRO, M. D.

On the Chemical Knowledge of Tartar Emetic.—Tartar emetic is decomposed by alkalies and the stronger acids, and a precipitate is formed of oxide of antimony. This caused several chemists to doubt the accuracy of the formula for tartar emetic: $R\,O\,Ta + Sb_2\,O_3\,Ta$. On this account, Dr. Schweizer has instituted several experiments, which tend to elucidate the subject. In order to decompose tartar emetic, he selected ammonia from among the bases, and nitric acid from the acids, because the separated oxide of antimony is almost completely insoluble in an excess of these substances, which can easily be removed by heat. *Action of ammonia on tartar emetic.* If you put ammonia into a perfectly saturated solution of tartar emetic, the latter becomes cloudy in a few minutes. A flocculent precipitate of oxide of antimony is formed, and gradually increases. The precipitation takes place immediately in heat. Notwithstanding an excess of ammonia, the liquid filtered from the precipitate still contains oxide of antimony, because it is soluble in alkaline liquids, but it amounts to so small a quantity, that it can only be regarded as an impurity of the tartrate of ammonia, which can be separated from the filtered liquid as a crystalline precipitate by means of alcohol. From one hundred parts of tartar emetic ammonia precipitates 43,35 parts of oxide of antimony, and in the filtered liquid only forty-one per cent. of the latter oxide is contained, as has been shown by precipitation with sulphuretted hydrogen. This result closely agrees with the analysis of Dumas, who found in tartar emetic, 44,86 per cent. of oxide of antimony. II. *Action of nitric acid on tartar emetic.* Nitric acid immediately produces in the solution of tartar emetic a considerable precipitate of oxide of antimony, which is increased by heat. But all the oxide of antimony is separated by this re-agent. Dr Sweizer always found tartar emetic in the liquid decanted from the precipitate, which could be precipitated by spirit of wine; besides the products of decomposition, consisting of tartaric acid and nitrate of potass. The precipitate obtained by nitric acid from the tartar emetic is not a pure oxide of antimony, for Sweizer found it to contain nitric acid, as basic nitrate of oxide of antimony. He convinced himself at the same time, that nitric acid added in excess removes, by the help of heat, not only oxide of antimony, but also potash, thus liberating tartaric acid, which again acts as a solvent on part of the precipitate, re-producing tartrate of oxide of antimony. The decomposition of tartar emetic proceeds more quickly, when the quantity is small, and the solution much diluted. Larger quantities and concentrated solutions are only partly decomposed. When the author decomposed the diluted solution of a small quantity of tartar emetic at a low temperature, the precipitate of basic nitrate of antimony amounted to 41·20 per cent. of the weight of tartar emetic employed. Also, by decomposing it with hydrochloric acid, a thick caseous precipitate resulted, as a basic chloride of antimony, which was re-dissolved in an excess of hydrochloric acid. The preceding experiments lead to the following conclusions:—1st, that in the action of alkaline bases on tartar emetic, the base employed takes the place of the oxide of antimony, which is then precipitated; 2d, that in the action of powerful acids on tartar emetic, all the oxide of antimony is precipitated with the acid employed, as a basic salt, by which means bitartrate of potash is formed, but that an excess of the acid employed causes fresh decomposition; 3d, that consequently, the whole quantity of oxide of antimony exists as a base in tartar emetic, and thus the stoechiometrical formula—$R\,O\,Ta + Sb^2\,O^3\,Ta$, is correct.—(*Dr. Schweizer, of Zurich, in Buchner's Repertorium.*)

On the Pharmacology of Quinine.—Desiderio, of Venice, instituted numerous experiments on sulphate of quinine, of which we shall mention the following:—1st, one scruple of the sulphate of quinine, in honey, suffices to kill a rabbit. The fatal effect is accelerated by acetate of morphia and by alcohol, but retarded, and even prevented, by laurel-water (aqua Lauro cerasi). Venesection was a more efficacious preventive. Rabbits, in which all the characteristic symptoms of poisoning by quinine were already developed, were perfectly restored by venesection. Pulv. herb. digital. purp. also proved curative as an antidote. These experiments were confirmed by Desiderio's observations on men. According to him, the effect of quinine on the organization is of a phlogistic nature.—(*Buchner's Repertorium.*)

Lesion of the Spleen remarkable in a Medico-Legal View.—A female, 37 years of age, after having been sickly for about eighteen months, was struck by her paramour with a stick on the back and left lumbar region. She complained of violent pain, fainted, and died six weeks afterwards. No trace of injury could be perceived externally, but in the abdominal cavity from six to seven pounds of yellowish, cloudy, and pus-like liquid were found, intermixed with flakes; the peritoneum dull, injected, and covered with yellowish, friable layers of fibrine. The liver atrophied; the *spleen-capsule* separated from the convex surface of the organ; below this, a resisting blackish-brown clot of blood, and a reddish-yellow coagulum of fibrine of the thickness of 1" was found, small lumps of which (of the size of beans) penetrated into the substance of the spleen to the depth of ¼". The kidneys showed a degree of degeneration indicative of Bright's disease.—(*Dr. Fritz, of Vienna, in Oester. Medic. Wochenschrift.*)

On the Mutual Differences in Structure between the Right and Left Ventricles.—In examining the heart the author found accidentally that the mean of a great many measurements as regards the parietes of the right ventricle amounted to exactly half the diameter of the analogous parts of the left ventricle. Proceeding from the conviction that the proportions of all our organs are based on mathematical calculations, he pursued the subject further, and obtained the result, that the mass of the right ventricle (in a normal state) is to that of the left ventricle in the proportion of one to two. This investigation can be performed in three different modes:—1° by measuring the thickness of the ventricular parietes in as many points as possible; this method is the most simple, but also the most unsafe. 2° by determining the volume; for this purpose the heart is divested of its appendages; the auricles are cut off from the ventricles at their points of insertion, and then the ventricles are separated. The latter is done in the following manner: the knife is passed round from the ostium venosum dextrum close to the septum ventriculorum; thus the whole wall of the right ventricle is exactly separated. The same is then done on the left side. Thus three pieces are obtained; the two ventricles and the isolated septum. The volume of each of these three is ascertained in the following manner: a glass-cylinder of proper capacity is placed on a horizontal table, and filled by means of a properly graduated measure, with a certain quantity of water. One side of the heart being now put into the cylinder, the level should be marked with a dash. The cylinder being then emptied, and again filled with water as far as the marked line, let the quantity of the liquid be again decided by means of the graduated measure. If the volume of the first quantity of water was = a, and that of the second quantity = b, the volume of the examined piece of the heart must consequently be = b—a. Having obtained by this method the volume of the right ventricular paries = a, that of the left = b, and that of the septum = c, the latter must be divided. As much of the septum ought to be attributed to each ventricle as corresponds with their respective volumes. If, therefore, the septal part of the right ventricle be = d, and that of the left = e, d must be in proportion to e as a to b (d : e = a : b). The following will then be the calculation:—Since a + b : c = a : d, we have $d = \frac{a c}{a+b}$ by the same reasoning we obtain $e = \frac{b c}{a+b}$ We thus have for the right ventricle in the whole $a + \frac{a c}{a+b}$ and for the left $b + \frac{b c}{a+b}$ Or if we put, for the purpose of facilitating the account, a : b = l : m, b is = a m, and thus $d = \frac{a c}{a+b} = \frac{a c}{a+am} \frac{c}{m+l}$ we obtain for $e = \frac{b c}{a=b} = \frac{a m c}{a+am} = \frac{m c}{m+l}$ Thus m + l : l = c : d, and m + l : m = c : e. It naturally follows that $a + \frac{c}{m+l} : b + \frac{m c}{m+l}$ is = a + d : b + e = a; b,

that is to say, the proportion of the two ventricles is not altered by the septal division (3). *The determination by weight.*—The heart is divided as above, each piece exactly tared on a good scale, and the whole calculated as detailed in number 2. The mass of the right ventricle standing to that of the left in the exact proportion of 1 to 2, it may be concluded, that in equal intensity of contractions the muscular powers will exhibit an analogous proportion. The hydrostatic blood-pressure of the pulmonary artery must amount to half the hydrostatic pressure of the aorta, and the whole resistance of the bodily circulation must be exactly double that of the pulmonary circulation.—(*Dr. Valentin in Henle's Zeitschrift.*)

PROGRESS OF ENGLISH, ITALIAN, AND AMERICAN MEDICAL SCIENCE.

Use of stimulants in palsy.—Dr. Blackmore says that he has little faith in the use of stimulants in the treatment of palsy. They have been supposed to do good, when the real benefit was from nature and time. People have recovered just as well without them, and they have used them without the least benefit. Stimuli are little to be relied on in hemiplegiac palsy; in the palsy of the legs from cold, and in partial palsy from the mineral poisons, they have been useful. External stimulants are safer than internal, and there is a greater chance of success from them. Sulphuric acid with oil has been applied to the skin; it is, in his opinion, useless. Ammonia mixed with eight parts of oil, is a better stimulus, as it is not necessary to produce permanent inflammation on the skin. Ammonia applied to the nostrils is dangerous. Sea salt is also used, so is brine; as a rubefacient it is of inferior efficacy to the linimentum ammoniæ. Volatile oils are powerful stimulants; as oleum succini, petroleum, terebinthina. Dr. Blackmore uses mustard most commonly: sinapisms induce inflammation, which may run into gangrene; they will induce inflammation in one hour; in general they are safe; a blister is, however, preferable. Stinging with nettles also is used for palsy of the limbs. Friction with a flesh-brush, or a rough flannel cloth, or a horse-hair cloth, is a powerful stimulus to the nerves and blood-vessels of the skin, and it promotes the circulation. Some physicians impregnate the flannel with aromatic steams, or dusts, as those of storax and benzoin: patients then think more of them; the friction is the most powerful part of the remedy. Heat is, in general, the most powerful of all stimulants; by it life is supported. Warm bathing is used, and the hot mineral waters, as the Bath waters. A safe way of applying it is the warm pumping. Cold is sometimes a stimulant; this is seen in dashing cold water over people to rouse them from syncope. The cold bath is used in the cure of palsy, supposing it to be a tonic. It is stimulant only from intense cold made by a shock; cold permanently applied is a sedative, and would benumb the parts; a transient sudden application of it is followed by an increase of heat all over the surface, from the increased action of the heart and arteries. The plunge bath is rather an ambiguous remedy; and cold applied to the extremities may drive the blood to the head, and bring on a fresh attack of palsy; the shower bath is safer, and more likely to be effectual; but the feet and legs may be chilled by the cold water. Electricity is a powerful remedy in the palsy of water-gilders from quicksilver; and it is applied to the cure of palsies of every kind; but it is doubtful whether any one with palsy, not from mineral poisons, was ever cured by that stimulant. The sparks are safe; the shocks are not equally so. The difference in these two modes is only in degree. Exercise, so as not to produce fatigue, is a very excellent remedy; strength will be gained by it, but it must not be violent. Some recommend the fumes of burning alcohol to be directed to the palsied limb; but no reliance can be placed on it. Internal stimuli are of less use, and more dangerous than the same substances used externally. Some give ten grains of carbonate of ammonia; others give mustard or horse-radish. The patient may use it for a condiment; but it is doubtful if the stimulant in the stomach has a direct effect on the palsy. Infusum raphani is diuretic, and may stimulate the absorbents in the brain to carry off the effused serum. Aromatics are used, as pepper, and the essential oils; their stimulus is too great, too permanent; that of carbonate of ammonia is sooner over. Some give alcohol, as in the compound tincture of cardamoms, and the aromatic spirit of ammonia; it cannot do any good.

Vessels in fat.—At a meeting of the Microscopical Society, Mr. Smee read a paper on vessels in fat smaller than the capillaries. He commenced by saying that although it was extremely difficult to ascertain precisely the original size of the capillaries, he was about to describe in the present paper another system of vessels so much smaller that it is impossible to attribute their diminutive size to any shrinking of those vessels; they are given off from them, and are distributed at every angle of each cell of fat. To these vessels he proposes to give the name of vasa adipis, as clearly pointing them out as appendages to fat, and also as preventing their being mistaken for the vasa across of some anatomists; the existence of which is, in his opinion, very problematical. The vessels now described are very minute, measuring from about 1-10,000dth to 1-25,000dth of an inch in diameter. They are found in every kind of fat when in its highest state of development, but do not appear until then. They exist only in fat the globules of which have assumed their polygonal form, so that it would appear the last process for the development of fat in its perfect state is the production of these minute appendages to the capillary system. It must, however, be borne in mind, that, although the term vessel has been applied to them, no evidence whatever can be adduced either of the existence of a cavity, or of distinct walls. The term vasa is here applied to denote that a certain part exists in a definite position with certain boundaries, permeable by fluid injections, and possessing generally tolerably regular dimensions. It would also appear that their formation depends upon the two sides of contiguous vesicles leaving at their angles a little space, which becomes converted into one of these minute vessels. Nothing has been ascertained with respect to their office.

Gonorrhœa.—In a paper entitled Statistics of the Edinburgh Lock Hospital, published in the *Northern Journal of Medicine*, Dr. Skae and Mr. Benbow, state with respect to Gonorrhea, that its treatment was almost entirely local, consisting, in the few cases which presented inflammatory symptoms, of scarifications and warm water injections, and in the others in the use of stimulating injections, consisting of solutions of sulphate of zinc, sulphate of copper, alum, acetate of lead, and decoction of oak bark. In chronic cases, mostly of long standing, advantage was occasionally obtained from the introduction of bougies coated with citrine ointment; more marked benefit, however, in similar cases, was derived from plugging the vagina with tampons of lint saturated with some astringent lotion; in others, again, the introduction of the nitrate of silver, in substance, into the vagina or uterus, was followed by immediate and decided amendment,—so much so indeed, that in two cases, one of them of two years' duration, a complete cure was effected by a single introduction of the caustic. In each of these cases the discharge proceeded both from the uterus and vagina. With regard to the efficacy of internal remedies, they tried numerous experiments with cubebs and copaiba, and are satisfied that neither have any effect upon gonorrhœa in the female. Even in one case where the discharge proceeded from the urethra, the copaiba, contrary to the opinion of M. Ricord, did not appear to have any effect. In chronic discharges from the uterus and vagina, apparently of a leucorrhœal character, they administered pills of sulphate of zinc in a great number of cases, in others they tried the ergot of rye, and in others the tincture of cantharides. From the two former they observed no marked advantage; the latter, however, was found very useful in a majority of instances. In obstinate cases, a cure was sometimes effected after the application of blisters to the sacrum; and, lastly, where the uterus presented much congestion, they found great use from scarifications of the cervix. With respect to the diagnosis between gonorrhœa and leucorrhœa they describe the characters laid down in works on forensic medicine as extremely fallacious. Gonorrhœa, it is said, affects the lower part of the vagina only, while leucorrhœa proceeds from a higher source. This may be true in certain recent cases of gonorrhœa, the result of violence; but it is by no means true in the great majority of cases. In many instances which they have seen of the disease in its acute stage, the mucous membrane of the vagina was inflamed throughout its whole extent, and also that of the cervix uteri; while a discharge exactly similar to that secreted in the vagina was also seen issuing from the os uteri. And in chronic cases, on the other hand, so far from this statement being accurate, they believe that the discharge of gonorrhœa proceeds principally from the *upper* part of the vagina. It may be said that the characters of the discharge will enable any one to distinguish between the two affections. This may also be true in some instances; the thin mucous discharge of the first stage of gonorrhœa, and the purulent discharge of the stage immediately succeeding, are certainly distinctive if taken in conjunction with the other signs of inflammatory action, and are, no doubt diagnostic. But when the affection has assumed a chronic character, it is not distinguishable from leucorrhœa, either by reference to its seat or the character of the discharge; the discharge in both instances is the result of a similar condition of the same membrane, which in some cases is pale and relaxed, in others livid and congested. Lastly, they have repeatedly inoculated with the matter of gonorrhœa without in a single instance obtaining a positive result, their experiments in this respect being in accordance with those of M. Ricord and others.

Inhalation of Oxygen in Asphyxia.—Dr. Wilson in the *Northern Journal of Medicine* recommends the inhalation of oxygen in cases of asphyxia as superior in its application to common air, and advises its disengagement from the chlorate of potash with one fourth or one fifth of a metallic oxide. There are numerous weighty objections to its use.

County Asylums for Lunatic Paupers.—In an article in the British and Foreign Medical Review, it is stated that these are erected and paid for by county rates. The great expense of their construction has prevented the erection of others. Some have cost as much as £200 per head for those they will accommodate, whereas the average expense of a union workhouse is £40 a head. Half of this large expense seems to have been caused by making the buildings fire-proof, and from the number of separate cells. These asylums should be placed on high ground, on a dry soil, with cheerful prospects, where there is a plentiful supply of water, and proper drainage, surrounded by sufficient land to give out-door employment and exercise, and not overlooked. The interior should be light and cheerful, and there should be light and warm galleries for exercise in bad weather. Some have these advantages, but in many they are partially or wholly neglected. The want of an ample supply of water in places where numbers are collected (many of whom are extremely dirty in their habits) is obviously a serious calamity, and the want of sufficient land is a great defect, as out-door employment (especially for the poor) is a great means of restoring the health of the mind, and of promoting tranquillity. Warmth, dryness, and ventilation are most important. At Stafford, since the adoption of an improved mode of ventilation and warmth, dysentery which was before prevalent, has not occurred, and the same disease has been removed in the Dorset Asylum since the floors which were damp have been taken up and relaid. In many of the older asylums the circulating steam or hot water apparatus has been introduced instead of open fires and stoves. In the Chester Asylum open fires in the day-rooms are still used "with a view to the enjoyment of the inmates, who much preferred them to a heating apparatus as being more cheerful." In the Kent Asylum, arrangements for ventilation (as should always be the case) were

executed with the building. The fresh air passes into a chamber beneath, where it is heated by passing over hot water pipes, thence it enters the galleries in a large volume near the ceiling, and is drawn off through holes in the floor into air drains communicating with fires in the cellar, which fires are entirely supplied by the vitiated air from the galleries and dormitories. This is said to answer perfectly. It is obvious, however, that a decided error has been committed in allowing the air to enter at the top and drawing it off from the bottom of the rooms, as the air vitiated by respiration is thus breathed over again, which it ought never to be. In day-rooms open fires properly guarded are preferable from their cheerfulness; for where low spirits and gloom and melancholy are the diseases of so many of the patients, every means should be taken to promote an opposite condition, and the mere question of expense should not decide the point. But refractory wards, galleries, and dormitories should be warmed by hot air, or by some system which combines warmth with proper ventilation, and in all new asylums this should be a part of the plan of the building, and not an after thought. Ventilation of the cells for the dirty patients, is often much neglected, and in some asylums the galleries which were not warmed artificially were extremely cold and comfortless. Sleeping-rooms should be built on one side only of a gallery, as they make it gloomy when on both sides; or if this latter arrangement is unavoidable, as in old buildings, recesses should be left between the rooms at intervals, lighted with windows on the outer wall. Light, if possible, should be admitted at the end of galleries. The commissioners are of opinion that good-sized sleeping-rooms, with a few beds, are preferable to single cells, as having a more free circulation of air, a more even temperature, and greater cheerfulness, but the writer considers a certain proportion of cells most desirable. Rooms on basement floors as a rule should not be used for lunatics, as they are cold, dark, and ill-ventilated. In some older asylums their cheerfulness has been improved by making them open on green grass slopes instead of areas. The commissioners incline to the opinion that galleries should be used for exercise only, and not as day-rooms, as the preparations for meals, placing and removing benches and tables interfere with the chief object. There is, however, another point at which this may be viewed. These preparations and changes make a break in the day which cannot be otherwise than agreeable to these poor idlers in wet weather, and it must be for some such practical reason as this that the galleries in the Kent Asylum, one of the best, are used as day-rooms, and that the resident physician of Hanwell approves of their double purpose. The yards should have as much light, sun, and prospect as possible. Many in the older asylums are gloomy, from high walls, and neighbouring buildings. Every yard should have a shed for shelter from the sun.

Acute spinal myelitis.—M. Pescetto, Physician to the hospital at Genoa, has published in the *Gior. della Soc. Med. Chir. di Torino*, the particulars of an interesting case of acute spinal myelitis, accompanied with amaurosis. The patient was a man, aged forty-two, of robust habit, a convict in the galleys at Genoa for the last four years and a half, in which he worked as a spinner of ropes, and had during all that period enjoyed good health. He was often exposed, when in a state of perspiration, to currents of moist, cold air. In consequence, he began to feel flying pains through the whole body, especially in the back, with a sensation of weight in the occiput, and slight amblyopia towards dusk. He endured these premonitory symptoms without complaint, and with extraordinary resolution. In a few days the pains became intolerable, the amblyopia was converted into complete amaurosis, and, on the 14th of March, he was admitted into the Infirmary. On examination, he was found in the following state:—Features contracted, and expressive of great suffering; complete amaurotic blindness; dull, heavy pains, at the base of the cranium, nape of the neck, and between the shoulders; no sleep for several days, general uneasiness and restlessness; respiration difficult, torpidity of arms; decubitus on the back painful; pulse febrile, but variable and feeble, anorexia, constipation. Rachialgitis, with cerebral congestion, was diagnosed. He was bled largely from the foot, and was also purged. The next day, the sleeplessness continued; neck stiff, its motions accompanied with the most intense pain; convulsive twitches, occasionally, in the arms and trunk; the patient complained of a feeling of combustion in the head, and suffocation about the chest; the amaurosis continued in the same degree; the restlessness and cardiac anxiety were greater; pulse more regular, but hard and contracted. He was then bled from the arm, both morning and evening, the blood the next day exhibiting a tough, thick, buffy coat, with little serum. The symptoms were then aggravated in character; the restlessness and anxiety were converted into a kind of terror, accompanied with inexpressible oppression at the precordia. He was again bled from the arm, four-and-twenty leeches were applied to the spine, and tartarized antimony was exhibited internally. The report of the fourth day is that the blood of the previous evening still buffy, but contained more serum; the pains in the back and neck, which had, till now, been lancinating and heavy, were somewhat mitigated since the last bleeding, and a copious perspiration, which followed it in the course of the night; decubitus on the back less painful, but the cardiac anxiety was still alarming; the sleeplessness and amaurosis still continued; the tartar emetic potion was suspended, the system not tolerating it; it was replaced by a simple tisane. The patient was again bled twice, after which the pains diminished in severity, as well as the spasmodic contractions of the neck, back, and arms; there was less oppression, and vision began to improve. He still, however, complained of pain at the epigastrium, and the tongue was covered with a thick fur. He was again bled twice, after which he gradually improved, and ultimately quite recovered.

Gangrene of the penis.—At a meeting of the Royal Medical Society of Copenhagen, Dr. Muller, of Elsinore, read the details of a case of gangrene of the penis, followed by urinary fistula and death. The patient, a Prussian sailor, thirty years of age, was admitted into the Oresund and Elsinore Infirmary, in the following condition, which he referred to having fallen with a handspike in his hand, which struck him over the root of the penis. On examination, the skin on the erected and much swollen penis was found blackened and hard; in some places (as on the glans) ulcerated, where it was also painful to the touch. In the pubic region, surrounding the root of the penis, the skin was discoloured and hard. On the lower part of the belly a tumour was observed, stretching from the symphysis pubis to the navel,—which latter was much distended, it had the form of a bladder. There was no pain on pressure, in the seat of the original injury. The under part of the belly was scarcely pained by a heavier degree of pressure. The pulse was somewhat low (75) the tongue a little yellow; he was rather thirsty, and had had no sleep during the previous night. The contents of the bladder (four imperial pints) were drawn off by the catheter, and leeches applied over the region of the pubes. The patient was relieved, and had some sleep. On taking away a part of the blackened skin and cellular tissue, a deep suppurating sore was seen on the under side of the penis, in front of the scrotum, and in this a hard body was observed, which, on nearer inspection, was found to be a ring of some kind of metal. It lay round the penis, and at its root. After having carefully introduced a suitable instrument, under the ring, to wit between it and the upper side of the root of the penis, a vain attempt was made to take it off. A watchmaker's saw was however successfully used in cutting it through, and as the ring was not whole, but formed by overlapping ends, both halves were thus easily separated. The bore of the ring was scarcely one inch, the breadth one and a quarter to two lines, and the thickness about the same. At the place where the ends began to overlap each other, of which part was turned down, a wedge-like hook was found, which went scarcely half through the ring, supposed to have been produced in an attempt which the patient had made to cut through it. The urethra was found perforated at the bulb, by an opening of the size of a pea, through which flowed the urine, mixed with blood and pus. About half a pot (one imperial pint) of urine was discharged by the catheter. The patient died a few days after from the constitutional effects of the continual sloughing of the parts. Autopsy, twenty-four hours after death.—The urethra was found injured for four-and-a-half inches from its mouth; above two-thirds of its calibre were wanting in the extent of one inch, where the upper paries only remained. At the opening of the intestines a large quantity of urine mixed with putrid matter flowed out. The whole of the fundus and body of the bladder were found adhering very closely to the surrounding parts, so that it was not possible to separate them. It was altogether changed in structure and consistency, being soft. The colour was dark grey; all the membranes were thin, bloody, and in some places dissolved into a bloody gangrenous mass. At the cervix two openings were found, one the size of a silver shilling, the other like an eight-penny piece,—small ovals with round corners; also in the fundus several small openings were found, which seemed soonest to appear in attempting to loosen the bladder from the surrounding parts to which it was adhering. The bowels were covered with a coat of plastic lymph, which in some places resembled a pseudo-membrane of the thickness of thick paper; this was loosened in large pieces. There was also some liquid pus, but it was nowhere gathered in any large collection. The ileum on the side opposite the attachment of the mesentery, was partly injected. The remaining organs in the lower part of the belly, as well as those within the thorax, were sound. *,* The author, Dr. Muller, seems quite at a loss to account for the presence of the ring on the penis, the secret respecting which, he says, the patient carried with him to the grave. There can, however, be no doubt but that it was used for the purpose of onanism.

Fungoid Tumour of the Lung.—At a meeting of the Birmingham Pathological Society, Mr. Russell, jun. brought forward a specimen of fungoid tumour of the left lung, coexisting with fungus of the breast of the same side. The patient, a female, 41 years of age, was admitted into the hospital, under Mr. Hodgson's care. About twelve months ago she first observed the left mammary gland to be somewhat hard, and felt considerable pain in it, shooting towards the shoulder; various remedies were employed, but without any avail, for the tumour continued to increase until she entered the hospital, when it was larger than an orange, firm, but slightly elastic, moveable on the subjacent parts, but attached to the skin above; the nipple was retracted, and two or three glands in the axilla were a little enlarged, but were neither hard nor painful; the breast was exquisitely painful; the patient not much emaciated, but had an anxious and cachectic appearance. The breast and the skin attached to it were removed, but not the glands in the axilla, as they were considered to be merely sympathetic. The wound healed rapidly, the glandular enlargement disappeared, and she left the hospital apparently cured on March 24th. The tumour presented the appearance of fungoid disease. Four months afterwards she was again admitted, a tumour having made its appearance just above the old cicatrix; it was about the size of a walnut, hard, and very painful; she experienced also very great pain down the arm; there was no glandular swelling. It was again removed, and presented the same characteristics as the former one. It had not healed much more than a month when it made its appearance a third time. It continued gradually to enlarge until the beginning of last May, when, having received a blow upon it, considerable inflammation took place, and it increased more quickly than at any former period, becoming firmly fixed to the parts beneath, and also to the integuments above, which were reddened and distended, but not ulcerated until the latter end of November, when it had attained its largest size, measuring twenty-five inches in circumference, and fifteen inches over it. Ulceration now rapidly extended itself, the tumour threw up large and loose granulations,

which frequently furnished most copious hæmorrhage, until sloughing of the surrounding tissues took place, and nearly the whole mass thus separated, but was soon re-produced. The poor woman ultimately sunk exhausted. *Sectio cadaveris*, thirty hours after death. The tumour covered nearly the whole of the left side of the chest, extending from the third rib to below the level of the ensiform cartilage, and from the centre of the sternum backwards to the axilla; the whole of it was in a state of black slough, and when cut into, presented a tough and cellular appearance, containing some sanguineous matter. It was not connected with the ribs, but occupied those intercostal spaces over which it was situated. The pleura on that side was covered at its lower portion by a small quantity of slightly organized lymph; the lung was also much consolidated; and at the upper and back part of the inferior lobe, was a portion of fungoid matter, about the size of a walnut, soft and friable; the lung around it was inflamed, and infiltrated with serum. The right auriculo-ventricular valves of the heart were thickened and opaque, and a false membrane could readily be separated from the endocardium. The mitral valve was also thickened and fringed, together with the aortic valves along the fibrous margins, by numerous small warty vegetations; from one of the latter valves there depended into the ventricle a piece of organized fibrine, attached to the same part of the valve as were the vegetations. The liver was large, pale, and loose in its substance, and presented the characteristics of a fatty liver. The kidneys were large and rather congested, and the right contained a quantity of lithic acid, some of which was found in the ureter. The other viscera were healthy.

Pulmonary Apoplexy: Valvular Disease of the Heart.—At a meeting of the Sheffield Medical Society, Dr. Favell exhibited portions of lung, shewing circumscribed pulmonary apoplexy, and a heart, the left ventricle of which was in a state of hypertrophy, and the left auriculo-ventricular opening so contracted, that it would not admit the tip of the little finger; the orifice was surrounded by ossific deposit; the mitral valve was remarkably short, thick, and of a cartilaginous hardness. The patient from whom these specimens were obtained, was a female, aged thirty-seven, who was admitted into the Infirmary, March 14th. She stated that she had been out of health for several months, but only unable to work since the preceding December. Her chief complaints were cough, dyspnœa, and palpitation. The abdomen subsequently became enlarged, and afterwards the inferior extremities. She stated that she had never had rheumatism. At the period of her admission the countenance was exsanguineous and expressive of considerable distress; dyspnœa very urgent; inability to lie down; severe pain in the left side of the chest; cough, attended with copious bloody expectoration; pulse 120, very feeble; general anasarca. There had been no catamenial discharge since December. Impulse of the heart natural, apex beating one inch below the left nipple, and in a line with it; slight *frémissement*; dulness on percussion more extensive than natural; loud and prolonged blowing heard with the first sound, most distinct at the apex and a little to the right rib; the abnormal sound gradually diminishing as the stethoscope approached the base of the heart. Pressure between the intercostal spaces from the second to the seventh rib occasioned considerable pain, and the respiration was attended with a loud pleuritic *frottement*. Mucous and sibilant rhonchi were heard extensively over the chest, both anteriorly and posteriorly. Dr. Favell stated that the rhonchi and the pleuritic friction together, were quite sufficient to mask any murmur accompanying the second sound of the heart, which is always comparatively feeble.

Cerebral Disease.—At a meeting of the Sheffield Medical Society, Mr. Ray exhibited a portion of brain, showing great apoplectic capillary engorgement of the optic thalami, with extensive softening of the surrounding parts. The specimen was obtained from a young woman who died somewhat suddenly, after having suffered from anomalous cerebral symptoms.

REVIEW.

An Essay on the Philosophy of Medical Science. By Elisha Bartlett, M.D., Professor of the Theory and Practice of Medicine in the University of Maryland. Philadelphia: Lea and Blanchard, 1844.

Dr. Bartlett may fairly claim the merit of having written one of the best works in our common language on the Philosophy of Medical Science. He thinks for himself and expresses his thoughts in good, plain language. Take this for a specimen.

There seems to be a common feeling, that the facts, phenomena, and events, with their relationships, classified and arranged, consitute, not the entire science to which they belong, but only the *foundation* of the science. There is a feeling, that these facts and relations are to be used as elements, out of which the science is to be built up or constructed by what is called *inductive reasoning*. The feeling implies, and the avowed doctrine growing out of it often asserts, that the science *is in this subsequent process of reasoning* and not in the facts themselves and their relationships. We are constantly told, that the facts are to be used *as materials*, to be sure; that it is not safe to take for our materials anything but facts; that they constitute the *basis* of every science; but, after all this, the essential condition and constituent of the science is often placed, more in the process of reasoning, as it is called, than in the facts of their relationships. Now, what I wish to insist upon is this, that the science *is in the facts and their relationships, classified and arranged, and in nothing else.* The ascertained facts and their relations, classified and arranged, constitute, in themselves and alone, the science, and the whole science to which they belong. The science thus constituted is, so far, complete. No process of inductive reasoning, or of any other reasoning, no act of the mind can add anything to what has already been done. The only reasoning that has anything to do with the matter, consists simply *in the act of arranging and classifying the phenomena*, and their relationships, according to their differences, their resemblances, or their identity. Words are things, and I cannot doubt, that much obscurity and confusion would be removed from our conceptions of the nature of the philosophy of science, if this long-abused term *inductive reasoning*, could be suffered to disappear from the language of science and philosophy, and if, for the indefinite and shadowy ideas which it so often expresses, or attempts to express, could be substituted those which are so clearly and obviously contained in this phraseology—*the classification and arrangement of phenomena and their relationship.*

This passage seems to us fully to justify the commendation we have just pronounced. It conveys the author's meaning in the clearest manner, and the principle contended for is one of considerable importance. For an illustration of it, as applied both to physical and medical science we must refer our readers to the work itself. The following are the leading propositions in relation to physical science which form the texts of the several chapters of the first part of the volume.

1. All physical science consists in ascertaining facts, or phenomena, or events; with their relations to other facts, or phenomena, or events; the whole classified and arranged. 2.—These facts, phenomena, and events, with their relations, can be ascertained only in one way; and that is by observation, and experience. They cannot be deduced or inferred, from any other facts, phenomena, events, or relationship, by any process of reasoning, independent of observation, or experience. 3.—A law, or principle of physical science consist in a rigorous and absolute generalization of these facts, phenomena, events, and relationship; and in nothing else. It is identical with the universality of a phenomenon, or the invariableness of a relationship. 4.—An hypothesis is an attempted explanation, or interpretation, of these ascertained phenomena, and relationships; and it is nothing else. It consists in an assertion, or a supposition, of certain other unascertained and unknown phenomena, or relationships. It does not constitute an essential element of science. All science is absolutely independent of hypothesis. 5.—Theory is one of two things, according to the manner in which the word has been used. It is either a generalization of phenomena, and relationships, and in this case, identical with a law, or principle of science; or, it is an attempted explanation of phenomena, and relationship, through the intervention of other assumed, and unascertained, phenomena, and relationships, and, in this case, identical with hypothesis. 6.—All classification, or arrangement, depends upon, and consists in, the identity, or similarity, amongst themselves, of certain groups of phenomena, or relationships; and their dissimilarity to other groups of phenomena or relationships. All classifications or arrangements are natural and perfect, just in proportion to the number, the importance, and the degree of these similarities, and dissimilarities.

These are the fundamental propositions relating to physical science. Having discussed and illustrated them in separate chapters, our author lays down a series of similar, and, in many cases, identical propositions in reference to medical science, which forms the subject of a second part. We subjoin the last three propositions which take the places of the last four already quoted.

An absolute law, or principle of medical science, consists in an absolute and rigorous generalization of some of the facts, phenomena, events, or relationships, by the sum of which the science is constituted. The actual ascertainable laws, or principles of medical science are, for the most part, not absolute, but approximative.

Medical doctrines, as they are called, are, in many instances, hypothetical explanations or interpretations merely, of the ascertained phenomena, and their relationships, of medical science. These explanations consist of certain other assumed and unascertained phenomena and relationships; they do not constitute a legitimate element of medical science. All medical science is absolutely independent of these explanations.

Diseases, like all other objects of natural history, are susceptible of classification and arrangement; this classification and arrangement will be natural and perfect, just in proportion to the number, the importance, and the degree of the similarities and the dissimilarities between the diseases themselves.

We wish we had space, for more quotations, and for longer comments upon this excellent work of Dr. Bartlett. We are especially pleased to find our children on the other side of the Atlantic measuring their Anglo-Saxon strength of intellect with difficult and lofty subjects of inquiry. They are evidently of the breed which produced our Bacons, our Newtons, our Lockes, our Herschells. They have the daring to cope with difficulties, and the strength to master them. They are beginning to display their power in all the points in which we have excelled. In divinity they have produced at least one great work, in sculpture they have just laid claim, if report speaks true, to one of the first artists of the age, and we doubt not that in medicine, and in all the sciences, they are destined to take a place by our side. Let them bridle their ambition, and moderate their Anglo-Saxon love of acquisition, and instead of laying claim to every territory which borders on their own, and incurring the risk of war by absurd and unreasonable pretensions, let them strive to emulate us in all the arts of peace, and in those pursuits

which make States really prosperous and happy. In such a race we shall be proud to have them for competitors, and to run side by side for that prize of high renown which is unstained by blood, and suffers no decay from time.

NOTICES TO CORRESPONDENTS.

A Fellow of the Royal Medical and Chirurgical Society, *complains that "it is not right that gentlemen, not members of the Society, nor belonging to the press, should be admitted to the meetings as visitors, night after night, and session after session, thus availing themselves of all the privileges of the Fellowship, without contributing in any way to the expenses." He has "understood that there is a special bye-law as to such unlimited admission, and asks "Why is it not put in force?"*

Gateshead.—*All members of the College of Surgeons will, if the Bill passes, be entitled to register as general practitioners, and as such to recover for medical attendance, retaining, at the same time, the title of "surgeon." Licentiates of the Apothecaries' Company before the passing of the Act, will be entitled to register as general practitioners, and recover for attendance also, but will not be allowed the title of "surgeon." Our correspondent had better now use his own discretion.*

X. Y., *if not duly qualified, would gain nothing by commencing practice before the Act passes, even if he considered it justifiable.*

We should recommend Dubitas *to take the fee offered.*

A St. George's Student *is informed that the* Medical Guide and Almanack *is published by* Renshaw; Mr. Ede's Works *by* Simpkin and Marshall; *and we believe* Wiley and Putnam *are the English Agents for the* American Almanack.

We have a very high opinion of the work mentioned by X. Y. R.

We are sorry to inform our correspondent from Llanfyllin, near Oswestry, *that no registration of students can take place till October next. We should have recommended him to register as soon as possible.*

We have received an immense mass of correspondence, which is necessarily postponed, much to our regret, to our next number.

THE MEDICAL TIMES.

SATURDAY, JUNE 21, 1845.

There is a tide! the affairs of man, &c.
SHAKSPEARE.

It is important that the Profession should know, that the carrying of the Medical Bill this session is not a certitude; and that the result may depend very considerably on the reception it *now* receives from the Profession, and the energy we *now* exhibit in making known our sentiments. Sir James Graham, not supported by the physicians—directly opposed by the pure surgeons—*id est* the twenty-four councillors—looked on with little favour by the druggists, and assailed with organized zeal by every empiric medical, and medico-political, in the state—will scarcely persist in his design, unless he learns from that portion of the Profession, for whose conciliation he has finally done so much, that he can be assured of their warm, generous and grateful support.

It is useless, it is worse than useless, to be slack in our support of the Bill, because it does not realise everything we believe necessary to a perfect organization of the Profession. With so many differences of opinion and theory, about what in *conception* is best for the whole; with so many conflicting interests in reference to what is practically desirable to us *individually*, it is almost impossible that at any time any one scheme of medical reform can appear to an equal number of us more faultless on the score of its positive excellency, and less to be opposed on the score of its omissions. We are so far fixed in *wrong*, anomalous and mischievous, that the journey to *right*, even with legislative omnipotence, cannot be made in a day. We must heal by degrees if we would remain without a relapse. The appetite for right will strengthen by degrees. An abstractedly perfect bill might do well enough for a few of the less impassioned philosophers; for the stomach of others it might be too much. Let us assimilate what Graham offers us, and we shall soon gain the power and inclination to inwardly digest more. Once fairly entered on the career of improvement, it will be difficult to say where we shall stop.

The aggregate meetings and requisitions about an object that when practicable, was overlooked and despised, have turned out, of course, so much moonshine. When the make-believe of imaginary *maladies* is foiled on that ground, because the patients address the legitimate doctor, he betakes himself to the *rôle* of the "make-believe" of imaginary *remedies*. Imagine *one* meeting of fifty or sixty, or a hundred gentlemen achieving, in June, 1845, what the whole Profession incessantly laboring through a score or more years, could not effect! An aggregate meeting reforming the College! The peasant who took a quack's purgative to find his lost ass, was about as well advised. The College will come to terms, the College will hear reason, when we bring another of our own along side of her, and teach her that she must sink or surrender! Not one instant before.

Let every gentleman really anxious for the union, well-being, and dignity of the whole Profession—Physician, Surgeon, or he who claims, in a large degree, to be both—the General Practitioner—now join together at this opportune moment to get passed a bill which, on the score of good government among ourselves, and high education for our successors, will do more to make us truly a learned, a liberal, and deeply respected Profession, than any other thing that has been done for us for a century. We are all, of whatever class, interested in professional amelioration, and we should all lustily put our shoulders to the wheel, to share in the important labour of giving the professional car a lift out of the rut in which it has been long imbedded. That effort successfully made, it will be time enough to discuss what we shall do next.

And let the Profession not overlook the stupendous toils undertaken, the stupendous labours accomplished by the National Association. That body has supplied for the Profession an immense *hiatus*. It has given us an executive, by which our energies have been wisely wielded, and a certitude guaranteed of immense future good. Let votes of confidence coming from every district that holds a single practitioner, support and encourage them in their disinterested labours for us; and let Sir James Graham and Parliament be taught, by individual petitions and memorials, that the Association enjoys the full confidence of the Profession. We beseech our brethren, at this critical juncture, to ACT—and act vigorously. Let them PETITION and MEMORIALIZE TO A MAN!

SINGULAR CASE OF WORMS.—At a meeting of the Sheffield Medical Society, Mr. Law exhibited some portions of lymph, (false membrane,) expectorated by a man labouring under bronchitis; and also a large round worm, (*ascaris lumbricoides*,) which had a hair tied round its middle, and was further tied in a knot. The patient from whom it was obtained, stated it had been voided in the state which it then presented.

PENCILLINGS OF EMINENT MEDICAL MEN.*

PH. PINEL.

Philip Pinel was born on the 11th of April, 1745, at Saint Paul, a village in the department of Jaru, not far from the town of Castres. His father practised medicine and surgery—his mother was a model of piety. They had a large family, but a small income. Philip Pinel was sent to the college of Lavaur, to commence his education; after which, being intended to take orders, he went to Toulouse, where he attended the lectures on philosophy of a professor, who made him a proficient in mathematics. Wishing to comply with his parents' desire, he commenced the study of theology; but his inclination did not lead him to this as a profession, and with his father's consent he left the university, and obtained a livelihood by giving lectures on arithmetic and natural philosophy. He competed in the Floral games, and carried off the prize; took, at his own expense, all his degrees in medicine; was chosen, for several years, assistant by one of the professors, and finally, on the 22nd of December, 1773, after passing with *eclat* the necessary ordeal, he was honored by the title of Doctor. Pinel, then 29 years of age, was far from being in prosperous circumstances! Having lost his father, he could expect no aid from his family, and the small income his lectures produced, rendered his position hardly tolerable, and made him fear for the future. The hope of improving his fortune, and still more the desire of increasing his scientific knowledge, made him quit Toulouse for Montpellier, where he arrived in 1775. The school of that celebrated town was then in all its glory; it is true, that Fizes and Sauvages were no more, but the knowledge of Barthez, the learning and eloquence of Lamarc, Leroi, Venel, and Gonan, as professors, and the talents of Vigaroux, Chaptal, and Fouquet, in private practice, shed on Montpellier a splendour which was reflected throughout Europe. Pinel had no sooner reached this modern Cos, than he found an asylum and protectors. He was received into the family of M. Benezeck, where he had as a pupil a young man, who has since become one of the most skilful officers of the engineers. But, notwithstanding the care and attention which he gave to the education of his pupil, he still had some time to devote to the completion of his medical attainments, to lectures on Chemistry and Natural History, to the study of the Greek and English languages, and to the composition of theses for young students. These theses, written in a correct and elegant style, were considered to be master-pieces of Latin composition, and were eagerly sought after. They were proofs of the wisdom and moderation of his mind, since he almost always chose a question of Hygiene for the theme, for if there be any shadow of probability or certainty in medicine, it is assuredly to be found in a subject of this kind. As to the more abstruse questions in medical philosophy, which at a future period he was destined to examine with such vigour, and which exercise considerable power over an inexperienced but imaginative mind, Pinel did not attempt to discuss them. Perhaps it was that, in his opinion, the systematic was equivalent to the hypothetical, and that there was something arbitrary which counterbalanced their utility, even in the most methodical classification. This kind of modesty was the more worthy of praise, inasmuch as, on the same subject, and with the same fund of knowledge, Sauvages, when much younger, had given an example of fortunate boldness, and if any man was to be Sauvages' rival, he it was who, at a later period, was destined to reform his most valuable work.

In order to shew the direction his character and ideas had taken, the following fact may be mentioned:—A young man was then at Montpellier, ardent in the pursuit of knowledge—impatient to produce something, and trying his strength on all subjects—writing poetry, comedies, tragedies, medical and philosophical treatises;—delighted,

* A series of eulogiums, from the pen of Dr. Pariset, the distinguished perpetual secretary of the Academy of Medicine, Member of the Institute, &c., will, after having been revised by the author, be published by his especial permission in the MEDICAL TIMES.

above all things, by a good classification of ideas, seeking to find symmetrical proportions in his own arrangements, and substituting, when necessary, imaginary or hypothetical for real proportions; in a word, captivated by what is called a system, and adopting nothing which did not present a regular order. Struck with the luxuriance of such a mind, and sorry to see so much natural talent wasted in chimerical conceptions, Pinel determined to cure his young friend of this species of enthusiasm.—"You are not in the right path," said Pinel to him, "but to be so, a little care only is needed on your part; come and read with me a few pages of Hippocrates, Montaigne, or Plutarch, every day." This proposition was cheerfully acceded to, and the two friends read Hippocrates during the day, reserving Montaigne and Plutarch for the evening. The perusal of these works was without restraint; it ceased from time to time, and was intermingled with digressions, remarks, and commentaries. This study, so diversified, drew, from its very variety, a charm which rendered it the more solid, and the more efficacious. For, however different may be the description of these distinguished painters of human nature, they possess a common character, by which they may be known from the descriptions of other writers. Their opinions take possession of the mind, elevating, enlightening, and strengthening it, and often all at once opening before it an immense horizon, shewing it the infinite variety of ideas, sentiments, passions, and infirmities of which the frail tissue of our frame is composed; finally, familiarizing it with that prodigious union of combinations and analogies, which, joining states so different from each other, proves, that this favours but indifferently systematic engagements. Under the tuition of such a master, and inspired by these noble geniuses, Pinel's young friend learnt to consider particular objects in their true light, and in their real position, with respect to the whole. Thus shaken, his ardour took another direction. He neglected erroneous systems to concentrate his powers on the exact observation of particular facts, for particular facts alone constitute certainties, and these are the sole grounds on which we can form our judgment. There are no fundamental truths but those they sanction, and without them, maxims are like a body without a soul. But what advantage did Pinel's friend, changed by the study of such masters, reap from the truths inculcated in their works? France has seen him shine, at a later period, by his knowledge and skill in her schools, in her academies, in various situations under government, and as a minister. His writings, and numerous services, rendered him worthy of the highest and most glorious recompense the august author of our constitution (the King) could bestow—to be chosen among the noble guardians of our liberty. He was named a Member of the Chamber of Peers—his name is Count Chaptal.

The country from which, in the same century, sprung Machiavel and Guiccardini, Michael Angelo and Raphael, Ariosto and Tasso, gave birth also to that eminent genius—Galileo, and produced in his school a sect of geometricians, who, after having submitted natural history to geometrical laws, endeavoured, after the example of Descartes, to extend them to medical subjects. The most distinguished and renowned of these was Alphonso Borelli, whose posthumous work on the movements of animals, was composed for Christina, Queen of Sweden,—a book full of original discoveries and views. It is there that, in explaining the double apparatus, or cords and levers, by which animals are enabled to move, Borelli showed, contrary to the opinions of the ancient writers, that in order to bring these organs into play, and enable them to overcome the slightest obstacle, an animal—a man especially—is obliged to expend an immoderate and disproportionate amount of force; but on the other hand, he proved, that by such an arrangement, the animal occupied less space; its shape is more elegant, its bulk less, its articulations stronger, and its movements more rapid, and that by this marvellous compensation, it has more power over surrounding objects, giving them, at the same time, less power over its frame. Admirable truths! which alone would be equal to a course of theology, of the glory of which, neither the critical observations of Parent, Varignon, and Hamberger, nor the works of Perrault, Vicq D'Azyr, and Barthez,* on the mechanism of animals, can deprive the name of Borelli. Following the example of Chirac and numerous others, Pinel became enthusiastic respecting so remarkable a work; he studied it attentively, in order to be enabled to apply the principles it contained, to the movements performed by the human frame. This produced a work, which was comprised under two heads, the one relating to the partial movements of the extremities, the other to the general movements of the whole frame. The former was completed before 1777, and was communicated by the author to the Royal Society of Montpellier; the latter was finished some years later, and reserved for the Academy of Sciences of Paris. Neither was printed. It is, however, probable, that the articles on Zoology, Comparative Anatomy, and even Surgery, published by Pinel at a later period, in various periodicals, were fragments of this work on the *Treatise of Borelli*, and unfortunately, they are the only fragments which have reached us.

Notwithstanding his natural modesty, which amounted almost to shyness, and his reasons for living at Montpellier, still an inward sense of his worth told Pinel, that he was destined to shine on a larger stage. His views were turned towards the capital, and in 1778, he left Montpellier, accompanied by an Englishman, whose talents in medicine have since placed him at the head of his profession. The two friends travelled without passports, and being distrusted by the functionaries of a village on the road, they were kept some days in prison;—an incident, indicating the modest manner in which they travelled. Having at length reached Paris, Pinel sought to gain his livelihood, and fortunately for him, he had the same resource as the celebrated Boerhaave before him, viz. *Geometry*. He had letters of recommendation to M. Cousins, an excellent geometrician, who, struck with his mathematical genius, sought to obtain pupils for him among the young men studying for the artillery or engineers. Pinel accepted two only, the fees received from them being sufficient for the necessaries of life, in order that he might have leisure for objects of another kind. Chance gave him for a lodging a small chamber, opposite to one occupied by a young man, who, like himself, pursued his scientific studies with indefatigable ardour. This was M. Desfontaines, whose travels, writings, and examples, abounding in sincerity, united to the amiability of his disposition, and the rectitude of his character, conciliated universal esteem. M. Desfontaines and Pinel were perfect strangers, but they saw one another daily, hourly, occupied by study, and this was sufficient to create in their bosoms a mutual inclination, and to give rise to one of those unusual friendships which in time become so necessary to existence. This friendship produced others. Pinel became acquainted with Roussel and Cabanis—Roussel, whose delicate touches caused his sketches to be admired, even after the sublime and more finished pictures of Rousseau and Thomas,—Cabanis, who by comparing the phenomena of internal and external sensibility, and by studying the effects produced by their mutual influence, laid the true foundation of human philosophy. Roussel and Cabanis formed part of the society received at the house of Madame Helvetius, and Pinel was by them presented there. He thus became a member of an assembly, where, joined to an agreeable freedom, there reigned the essence of politeness and wit, of which the remembrance alone remains, but which has conduced to embellish our judgment. With the number of Pinel's friends and acquaintances, the opportunities also of using the rich stores of his intellect increased. He wrote articles on medicine, natural history, moral philosophy, and political economy, for the *Journal de Paris*; the *Gazette de Santé* was placed under his direction, and its prosperity was for several years attributable to his exertions. Several remarkable articles on hygiene, which was still his favourite study, were, from time to time, inserted, and attracted special attention. In his critical remarks on the books which he reviewed, flashes of wit now and then appeared, proving that he could be satirical, had not prudence and the kindness of his heart prevented him. From 1754 to 1779, extracts from all the memoirs read before the various learned societies of Europe, since the period of their institution, had been published in thirteen 4to. volumes. This publication, worthy of a better fate, had ceased to appear, and the philosophical transactions particularly had only been continued until the year 1694, leaving an important *hiatus* to be filled up. These transactions, in an abridged form, had recently appeared in English, and their translation into French was commenced and published in 1786, 1790, and 1791. Of the fourteen volumes of which they are composed, the studious Pinel translated three; the first on Chemistry, the second on Anatomy and Physiology, and the third on Medicine and Surgery; he also assisted in the compilation of a fourth, on Materia Medica and Pharmacy. It cannot be denied, however, that in the co-ordination and choice of subjects, the English author did not possess the judgment and method necessary for so vast a subject; for we find in the work needless repetitions, redundancies, and long articles taken from French authors. But, in spite of these faults, the reader is gratified by the perusal of numerous highly interesting articles, from among which we quote the three following:—*The first* relates to the comparative experiments performed in 1721 and 1722, at Marseilles and Montpellier, with the bile. In some cases, it was taken from the bodies of individuals who had died of diseases common to the country; in others, from the bodies of persons who had died of pestilential diseases. In the former cases, this fluid, injected into the veins of strong and healthy animals, produced serious and even fatal consequences, but without causing gangrene, buboes, or any of the characteristic symptoms of the plague; in the latter, on the contrary, it caused a disease truly pestilential to appear with the utmost rapidity. *The second*, enriched, in common with many others, with annotations by Pinel himself, relates to a woman condemned to death and executed. At the *post mortem* examination, she was found to have conceived a short time previously, and there was thus an opportunity of proving, contrary to the opinion of Buffon, the truth of Valisneri's ideas on the mechanism of generation. An ovum, about to be detached from the right ovarium, adherent to it only by a pedicle, and surrounded by an unctuous and transparent fluid, was embraced by the extended digitations of the Fallopian tube, of which the dilated extremity, bent downwards, was spread over, and strongly adherent to the surface of the ovarium. *The third* is the description of that extraordinary malformation which would appear to confirm, in some cases, the fable of the Androgynes, or that of Tiresias, and which, by uniting the rudiments of both sexes, seems to complete neither one nor the other. This imperfection, observed by the ancients in men and animals, has always been a source of controversy. In 1786, Pinel had an opportunity of studying a case of this kind, and gave a description of it in the *Journal de Physique*, and in the *Recueil de la Societé Medicale d'Emulation*. This case, not more extraordinary than those described by other authors, teaches us nothing new on hermaphrodism; but, considering the question further, Pinel concluded, that the authors who had examined it, by confining their opinions to their own observations, believed too readily what they saw to be the limits of what was possible; and after impartially passing, in review, the most authentic, but at the same time contradictory, opinions, from Aristotle and Pliny, to Buffon and Haller, he stated, that the problem was yet unsolved, and could only be decided by means of future investigations. This principle of reserve, frequently requiring boldness, Pinel employed in the examination of a fact not less astonishing,—we mean the ossification of the brain, discovered in oxen, some of which had retained all their pristine vigour. The first of this

* *Nouvelle Mecanique des Mouvements de l'Homme et des Animaux*, Carcassonne, 1798, in 4to.—See especially the remarkable works of G. and E. Weber:—*Traite de la Mecanique des Organes de la Locomotion*, translated from the German by Jourdan, Paris, 1843, in 8vo., with an atlas of 17 plates, in 4to.

kind was mentioned by Bartholine, who gave it on the testimony of another, but stated, that he did not know how far we might rely on its correctness.* The second, in 1703, by Duverney, to whom the diseased organ was presented. Valisneri reproached him with being credulous, although Malpighi, in 1670, saw and described a similar case. Such is the fate of every extraordinary fact; it is at first looked on as incredible, and obtains belief only on repetition, as if what we are pleased to call our judgment is, after all, only habit. Be this as it may, other brains, ossified to the consistence of the hardest marble, were observed in Saxony by Petschells, and in Scotland by Simon. The last seen at Paris was presented by H. J. Baron to the Academy of Sciences, and it was this brain, preserved by M. Deyeux, which Pinel examined, and on which, in 1793, he wrote a memoir, terminated by this dilemma:—"These masses are either brain metamorphosed into stone, as the vascular net-work, whose ramifications are not destroyed, seems to prove; or they are tumours, which growing slowly, so as to fill the whole of the cranial cavity, cannot fail to exercise considerable pressure on the cerebrum; in either case, it is extraordinary that life should continue, and still more so, that the animal should seem in good health." But in what state were the origins of the various cerebral nerves in animals thus affected? This was not ascertained—a circumstance which, in Pinel's, and we may add, in our own opinion, is ever to be deplored. But constantly attracted to the wonders of animal mechanism, Pinel sought to explain those of the osseous system—of that frame-work which, by its arrangement, determines the external appearance of animals, and which, at the same time solid and mobile, makes an admirable use of these two opposite qualities, which, increasing and multiplying its strength by its curves, receives, sustains, protects, and maintains in their position the various organs, and which, when put in motion by the springs it gives attachment to, leads in different directions its several parts, whether it be to support the animal on the soil, to permit its moving with agility from one spot to another, or to launch it into the air with rapidity and force. This spectacle, wonderful to a mind capable of appreciating it, caused Pinel to discover what had escaped Borelli's observation,—that the power which the latter supposed to be lost in motion, aids, as a necessary effect, by strengthening the articulations, to give a more solid fulcrum to the bones which form them; thus rendering their motions more sure and energetic. On the other hand, by studying the articulations with greater care, Pinel became convinced, that practitioners in general were not familiar with their mechanism, and that, from the want of having an exact description of them pourtrayed in their minds, the most skilful form erroneous ideas concerning the reality of luxations, and the manœuvres necessary for their reduction. In order to prove the correctness of his opinions, Pinel wrote memoirs on the different luxations, which he presented to the Academy of Sciences in 1785 and 1786, and extracts from which are to be met with in various periodicals. These memoirs are only be considered as proofs of geometrical, rather than surgical skill, and were of little use practically. Finally, the more Pinel studied the structure of animals, the more his mind became convinced of the important fact, that in the living creature the parts are strictly dependent on each other; so that, between its wants and its faculties, its organs and the liquid which forms them and repairs their losses, its nervous system and its muscles, its blood and the products which during the circulation are eliminated from it, as well as the food from which it is formed, and which is left to the animal's choice, and again, between this food and the secretions destined to dissolve and vivify it; in fact, between all parts of the animal frame there exist powers, correlative, hidden and impenetrable, though real, established purposely the one for the other; from which, in each animal, an harmonious whole results, and whence it may be drawn, as a final conclusion that, as all these parts have a mental affinity, it would be sufficient for a skilful eye to discover one in order to know the remainder. But the greater number of the component parts of an animal have no connexion with surrounding objects; and the only one, placing the animal in relation with these objects, which may be always consulted, and which, from the solidity of its texture, and the pre-eminence of its forms can always suffice for the wants and habits of the animal (at least in certain classes) is, the osseous system. And it is by that portion of this system which bounds it anteriorly (the maxillary bone), by the arrangement of the teeth and the structure of the articulation of the lower jaw, which is firm or loose, as the animal is carnivorous or herbivorous, and which presents in different animals, a thousand different modifications of the parts composing it, that Pinel proposed to distinguish the species. This method he followed with a certain degree of success on a great number of quadrupeds, and supported it by a memoir which he wrote on the subject. But it was easy to perceive, even in the classification proposed by Pinel, that the idea which directed him had not sufficient compass, and would soon vanish in his hands; a praiseworthy though sterile effort of the mind, for which more learned classifications have since been substituted. This subject, however, gave origin to three interesting articles from the pen of Pinel; *the first*, on the structure of the head of the elephant; *the second*, on the retraction of the claws in the carnivorous animals; and *the third*, on the best method of preserving quadrupeds and birds for anatomical collections, so as to retain their natural colour, shape and attitude, in short, to give each the appearance it had when alive. Such a variety of memoirs on the same subject, rendered their author justly celebrated, and it is, said, that the professorship of comparative anatomy having become vacant, Pinel was named to compete with G. Cuvier, who, even then, was without a rival. Cuvier was elected, a fortunate choice, favourable to Pinel's celebrity, and from which both natural history and medicine reaped great advantages.

* *Vide* Barth. Aut. 3, Phist. 8.

(To be continued.)

TO THE PRACTITIONERS OF MEDICINE AND SURGERY IN THE PROVINCES.

Gentlemen,—Since I last addressed you, two important documents have been presented to the profession;—viz., a "statement" from the Council of the College of Surgeons, and a letter from Mr. Guthrie, the Chairman Elect of the banquet to be given at the Freemasons' Tavern. The majority and the minority in the Council have severally declared their sentiments; and it would certainly puzzle an adroit casuist, to determine in which scale corporate liberality weighed the heavier. Their opinions are so nearly balanced, that the opposition of the redoubtable champion of liberality to his brother councillors, must remain an enigma. It was a problem with the old schoolmen, whether *a pig being driven to market was held by the man, or by the cord in the man's hand!* Now it is some such a subtle question as this,—a similar hair-spliting distinction, that has caused so much wrath and rancour among the learned disputants in Lincoln's Inn Fields. If silly people will indulge in such follies, it is not, at all events, very prudent to publish them to the world.

The supercilious insolence of the former document exceeds anything that has yet been perpetrated against decorum by its authors; and while it defeats every hope of an amicable arrangement with the College, it reflects indelible disgrace on the Council, who in the narrow and exasperated spirit of disappointed selfishness, have so far forgotten the dignity of their office and the honour of the profession, as to stigmatize by an opprobrious epithet the majority of their brethren, to decry their just position, and to depreciate their acquirements and general usefulness. Nothing could have been conceived in worst taste,—nothing could more glaringly display the bitter dislike which the Council entertains towards the general practitioners,—the exclusive, contemptuous and grasping spirit in which they have hitherto acted,—their resolution to persevere in this unworthy career, and nothing could have afforded a better comment on the labours of the National Association, or tended more effectually to convince the general practitioners of the necessity and justice of the movement which this body has, hitherto, so triumphantly carried on. It were a gross folly,—a mean dereliction from self respect to attempt any further diplomacy with this arrogant Council. Their days are numbered.

The coquetry in which certain gentlemen at the Freemason's Tavern have been indulging with the fascinating G. J. Guthrie cannot now serve the purposes of the profession. It would seem that the bashful *inamorata* was a long time discovering her sentiments, and declaring the terms upon which she would consent to the honorable alliance. The oracle has, at last, spoken;—and though sufficiently mystic in some respects, it does not require a sphynx to render it intelligible. It remains to be seen, whether after the letter now published and so ably commented on by the committee of the National Association, the gentlemen of the Freemasons' Tavern (I ask their pardon, if by their exertions, they have yet been enabled to form a Committee) will continue to co-operate with Mr. Guthrie, and attempt to sell, by a species of inverted auction, their most valuable principles to the lowest bidder.

I confess to you, gentlemen, that during my late experience of political life, I have seen such curious revelations, that I am no longer easily astonished;—and although I am satisfied that the pure integrity of the mass of my professional brethren would resent any dishonourable intrigues, yet I am always apprehensive lest a cunningly devised imposition should deceive and fetter their better judgment. The elements that have hitherto brewed the storm at the Freemasons' Tavern have been indeed of an extraordinary character;—and, truly, when the north and south winds meet, we can expect little less than a tornado.

The "modest author" (can he ever forget the source of this cognomen?) has forgotten his modesty;—the lovers have arranged their quarrels, and with the assistance of a very worthy practitioner, but still a harmless individual, whose greatest misfortune is, that he has had "his greatness thrust upon him,"—the present chairman of the movement, they have constituted themselves, what may be termed—*the unholy Trinity*; in which there is certainly a distinction of persons, but no unity of will, and whence, therefore, we can expect nothing but the most admirable confusion. There is an old adage, "misery makes us acquainted with strange bedfellows;" how far it receives illustration from the proceedings at the Freemasons' Tavern the profession can determine. When I reflect on the constituents of that movement, I am ludicrously reminded of the regiment of ragged recruits with which Sir John Falstaff marched through Coventry, and who, to employ their leader's expressive phraseology—were "the cankers of a calm world, and a long peace."

I apprehend that no rational mind can entertain the slightest hope of an union with the college of Surgeons on liberal terms. Do you expect that the government will accede to this proposition? Sir James Graham said, in my hearing, that *he* would not apply to the Council of the College for their consent to a modification of the charter;—and he is not likely to succumb to the Honorable Member for Finsbury, between whom there is an evident hostility. Can you place a blind reliance on the Council? They have clearly resolved not to apply to the government; and you may rely upon it the majority will never capitulate to the agitation of Mr. Guthrie, whom they must now regard with feelings of jealousy and distrust, and esteem little better than their declared enemy. And what hope can you indulge in the minority of the council of whom Mr. Guthrie is the champion? Let Mr. Guthrie answer for himself.

He is willing to grant the fellowship to men of twenty years' standing, not unconditionally, be it remembered, and by mere right of seniority,—but only in case they are *sufficiently respectable*, and are well esteemed by their professional brethren! And who will be the judges of this respectability and professional estimation? The Council of course? So that, by this scheme, the practitioners

of twenty year's, standing can be admitted to the fellowship, only under the approbation of the Council, by whom all bye laws regulating such admission will be made, and inexpressible hardships might thus result. Is this common justice?

Again, every fellow may be eligible for the council who has been "more than twenty years a member and fellow;" (rather mysterious!) whence I infer that a practitioner admitted to the fellowship at forty-six, must still be twenty years a fellow, and consequently more than sixty-six years of age before he can be eligible for the council! Ay, and even then he may be disqualified, if he practise pharmacy and midwifery in accordance with immemorial usage." Glorious liberality! notable reformer! How will the gentlemen of the Freemason's Tavern admire this? He does not whisper a syllable about the extension of the franchise, except to a certain number of gentlemen as before stated, nor the admission of members of different qualifications in the *reformed* College!

Can you, gentlemen, after this, persist in the delusion of a reform of the College of Surgeons? And will you thus risk all the advantages you may obtain by a steady support of the Bill and Charter, as sanctioned by the Committee of the National Association? I cannot believe that you will;—nay, I know that you perceive already the fallacy and folly of the new movement. I congratulate the profession most heartily on the renewed support which the National Association has lately received. I beg you to continue it; and by so doing vindicate the independence of your character.

By the last transactions of this Association it appears, that notwithstanding all the efforts of their enemies, the number of secessions during the last six weeks, has amounted only to one hundred and twenty-four, while the enrolments amount to one hundred and ninety-one, being an excess of one half above the number seceding. This is a highly gratifying fact, and truly encouraging to these zealous labourers in our cause. I trust that the number of withdrawals will rapidly diminish, and a generous confidence be restored.

Is it not, gentlemen, a more worthy thing to co-operate with your equals—your professional brethren—with men whose hopes and interests are identified with your own—and who can have no mean, sinister, and private interests to serve—who cannot have been goaded on by vanity and ambition; but who, sacrificing their time and money in the patriotic desire to employ the advantages of their locality and station for the regeneration of the profession, have, amid the blandishments of popularity, maintained their integrity inviolate—who have never been charged with a cringing servility to men of influence or office, but, on the contrary, have guarded their independence with a jealous courage, and a manly contempt of the consequences;—is it not, I ask you, a more worthy thing to lend your support to such men, than to be dragged captive at the heels of any individual,—no matter what may be his talents, his social standing, or his literary capabilities? And when, gentlemen, you are convinced that the objects advocated by such an individual are impracticable, is it not the very climax of folly to grant him your co-operation?

I believe that this movement has received a check,—a formidable blow from which it will not recover; the seductions of a public breakfast, and the company of a few members of parliament have not been sufficiently potent to allure the general practitioners of the country from the noble object of their labours. The press is a mighty engine of power,—the most glorious institution the world has ever known for the promotion of social advancement, but in proportion to its influence, is the necessity that it should inculcate truth, and the observance of that responsibility which attaches to those who preside over its amazing potentialities. Public opinion is not a mere automaton,—nor politics a juggle,—emancipation of mind has commenced,—intellectual enlightment is not a sudden sunburst,—the knowledge of right is a gradual revelation, but the rights themselves are permanent and indestructible, and have been gloriously vindicated by that very press which too often, for party purposes, seeks to embarrass and impede their enjoyment. It will not succeed,—a child may set an engine in motion,—but he must beware lest he be crushed under its weight.

There never was a profession of such a growing power and energy as our own,—that promised better, or could accomplish more,—that has contributed so much to science and social advancement, and that in pursuing the same path can fulfil a higher destiny. I cannot regard the rapid advancement of my profession in all the useful learning of the age, its increasing respectability and scientific character without the deepest satisfaction. I can discern in it the elements of future greatness,—the germs of incalculable social benefits,—the springs of honor, credit, and celebrity ready to burst forth, and carry it forward to the very first rank of intellectual progress, *all these advantages depend upon yourselves!* Will you abandon them? Such abandonment would be suicidal. Or would you slavishly accept from the hands of others what you are able to achieve for yourselves? I think I know you better.

I remain, Gentlemen, yours very sincerely,

GEORGE ROSS.

Kennington, June 10, 1845.

MR. GUTHRIE AND THE NATIONAL ASSOCIATION.

Some announcements of a Public Meeting to be held at the end of the month, under Mr. Guthrie, having reached the committee Association, the wrote to know how far he and the Council would bid to get back the good opinion of their members; the following is the answer:—

To Messrs. Bird and Ancell, Honorary Secretaries of the National Association of General Practitioners, &c. &c. &c.

GENTLEMEN.—I have the honour to acknowledge the receipt this morning of your letter of the 7th instant, and have great pleasure in replying to your inquiries. I have assured Mr. Bottomley, the chairman of a committee sitting at the Freemasons' Tavern, that I would preside at an aggregate Meeting of Surgeons to be held towards the end of the month, provided the requisition calling upon me to do so, was signed by one thousand members of the Royal College of Surgeons, and that the proceedings to be introduced, and which it was intended should be adopted, were first made known to me, and were such as I could support.

With respect to the changes which I think ought to be made in the Charter of the Royal College of Surgeons, and in the manner of carrying it out, I long since wrote my opinions to Mr. Propert and Mr. Squibb, two of your committee, and communicated them orally to Mr. Bird, one of yourselves, with the hope that your committee might have been induced to adopt some of them; and to ask the Council of the College of Surgeons to make only such reasonable concessions as would have led to an amicable adjustment of the differences which have taken place between the Council and a great majority of the Members of the College. Instead of doing this, the Committee of the National Association of General Practitioners called upon the Council of the College of Surgeons to do what they knew the Council as men deeply interested in the character and welfare of the Profession of Surgery could not do; and what the Secretary of State would not have permitted them to have done, even if they had been so allowed to do by their charter. I am therefore inclined to apprehend that in making such an application to the Council of the College of Surgeons, the Committee of the National Association neither expected, nor scarcely desired it should be complied with.

The answer of the Council of the College of Surgeons is perhaps as little to be commended; and it appears to me that these documents may be fairly considered by men of the world—such as the Members of the Committee of the National Association—to be only so much paper wasted, and both parties having thus felt each others' strength, may begin again to negociate if they please, without disparagement to the honor of either.

I am of opinion that all the Members of the College of Surgeons of twenty years standing, should be made Fellows, on complying with such conditions as the Council may require relative to their general respectability, and the estimation in which they are held by their professional brethren, and that all those who subsequently attain this standing should be annually advanced to the desired honor; Juniors should obtain it as at present by examination and fine. All precedence should be removed, and every Fellow should be eligible to the Council, subject to the usages which have existed from time immemorial, who had been more than twenty years a Member and Fellow; the ballot taking place according to the seniority of those who may have been duly nominated some fourteen days previously to the day of election.

The number of members of the College of twenty years standing not already Fellows is 1836; many of these might not seek the Fellowship, and many more would not be found eligible.

It is said by some persons, and the opinion is entertained in the highest quarters, that such an addition to the existing Fellows would swamp the College. I believe this to be an unnecessary alarm, which very little inquiry would suffice to allay. It is merely an apology for an injustice which imposes on those who are not aware of the honourable feelings which at present govern, and which I hope will always govern the Fellows and Members of the Royal College of Surgeons.

The Society of Apothecaries having expressed their willingness to be divested of the power they now possess of appointing examiners in physic and pharmacy, in consequence of their retention of it not being in accordance with the feelings of the profession at large; I would wish to consider how far it might be advisable to augment the Council of the College of Surgeons by ten members, to be elected by the Fellows from amongst those of their number, practising midwifery, with or without physic and pharmacy, who might be considered the most deserving of this honor. They might form a Court or Board of Examiners in these branches of science, under the authority of the Council, having their own chairman, and being independent of the Court of Examiners in anatomy and surgery, from amongst whom the President and Vice-Presidents of the College should be always selected.

No student should be allowed to practice legally for lucre, until he had passed both examinations, and thus the entrance to the profession of surgery, physic, midwifery, and pharmacy, would be by one common portal, in the simplest, and at the same time the most effective manner.

I am fully aware it is supposed, that the Council of the College must inevitably be swamped by such a second addition to their burthens, if they were so fortunate as to escape from the first submersion, but again I am of a different opinion, and would see the experiment tried, with much pleasure.

The Medical Bill will, if it become an Act of Parliament, altogether deprive the members of the Council of the College of Surgeons of every honorable, nay, respectable, function they at present possess. It will not leave them the power to add one sovereign to the salary of a servant without the sanction of the supreme Council. It reduces them to the station of keepers of their own library, and their own museum, and does not even permit those who are examiners to exercise a portion of the functions they now enjoy without molestation; for the *elite* of the surgeons of London are to be compelled to submit to the intrusion even of a Secretary of the supreme Council, during their examinations; and if he should not approve of the manner in which they are conducted, and the supreme Council should be of the same opinion, *their students are to be punished* until the examiners shall cease to be contumacious!

I apprehend that the worst enemies of the Council of the College of Surgeons could propose nothing that would more effectually "swamp" and degrade them than this Bill, should it become law.

In proposing to add to their number ten men of acknowledged character, and professional reputation, I do believe I am only recommending a means of immeasurably augmenting their influence, and of detracting nothing from their station, their su-

thority, or the safety of the great art and science of surgery.

The Medical Bill has been so much altered, and has become so essentially different from the propositions which were first entertained, that it more resembles a piece of patchwork, composed of a succession of small jobs adapted for the aggrandizement or for the advancement of the personal views and interests of the different parties concerned, than a legislative measure for the benefit of the whole community.

Whether it may, or may not become law, depends upon the forbearance of the Secretary of State, and it is to be hoped, that seeing the strong feelings which exist against it, he will withdraw it this Session of Parliament, and re-introduce it in the next, in a matured form, founded on principles more truly conservative, less arbitrary, and yet of a more liberal character.

In conveying to you these opinions, I need hardly say they are entirely my own, and have no reference whatever to those which may be entertained by the Members of the Council of the College of Surgeons collectively. I shall not presume to form an opinion as to what they may be hereafter disposed to do, although I am satisfied that if they are permitted to exercise a fair and free discretion on any matter submitted for their consideration, they will end by doing what will be found most advantageous for the public, and the profession of Surgery.

In conclusion I can only assure the Committee of the National Association of General Practitioners, that if I should have the honor of presiding at any meeting of the surgical profession, it will give me great pleasure to see around me as many of their members as may be able to attend; and I venture to hope that by mutual concession and forbearance we may be able to aid in the restoration of those principles of public liberty, and public justice, which have been, in my opinion, so sadly violated, in the charter lately granted to the Royal College of Surgeons, and in the construction of the Medical Bill, now under the consideration of Parliament.

I have the honor to be,
Gentlemen,
Your very obedient humble servant,
G. J. GUTHRIE.

[It is evident that Mr. Guthrie aims to save his council brethren in their own despite. We wish him joy of the thankless, but gigantic enterprize. Ed.]

MEDICAL MEETING AT THE LONDON TAVERN.

A meeting of the Tower Hamlets Branch of the Medical Association was held at the London Tavern on Wednesday evening, —— Snow, Esq., in the chair, to take into consideration the propriety of petitioning Parliament in favour of Sir James Graham's Medical Bill. The meeting was numerously attended (although the notice was very short), and the greatest unanimity prevailed. The minutes of a former meeting having been confirmed,

Mr. James Liddle, in an able and argumentative speech, moved the first resolution,

"That this meeting desires to express its concurrence in the general principles and features of the Bill for regulating the Profession of Physic and Surgery, as amended by Committee, and to convey to Sir James Graham its warmest acknowledgments for the liberality of spirit manifested by him in his endeavours to reconcile the various conflicting class and corporate interests in the profession."

This was seconded by Mr. Porter, and carried unanimously.

Dr. Gavin then said that he rejoiced much to see that the General Practitioners were on the eve of a separate incorporation—of being in fact, raised to an equality with the Royal Colleges. He was sure that under this arrangement the extended course of study and increased strictness of examination would tend to raise the future General Practitioners in the estimation of the public. He had to propose the second resolution,

"That the recognition of the General Practitioners as a distinct class of the profession, the provision made for their representation on the Council of Health, and their incorporation in a new Royal College, cannot fail to raise their respectability and position, and be most conducive to the best interests of science and humanity."

This was seconded by Mr. Holtman, who said he was convinced the meeting was unanimous, therefore he need not detain them after the able remarks of his predecessor.—Carried unanimously.

Mr. Samuel Byles, in rising to propose the third resolution, felt himself called on to allude, in terms of strong disapprobation, to a meeting held at another place, which was supported by a few members of the profession, unfortunately deluded by the sophistry of an individual who was well known as being able to make the worse appear the better cause. He was convinced that the following resolution would have the cordial support of the meeting—

"That at the present crisis, any attempt to effect an incorporation in the Royal College of Surgeons, while it cannot fail to be unsuccessful, as shown by the manifesto and statement recently issued by the Council, will, by promoting dissension and division among the General Practitioners, prove most hostile to their interests, and tend to prevent the present liberal measure of Medical Reform being brought to a satisfactory and desirable termination."

He felt positive, from a meeting at the Freemasons' Tavern, which he had himself attended, that the gentlemen who assembled there were not the men to destroy the College walls, although they might, by factious opposition, be powerful enough to disgust Sir James Graham. He was certain that now we must not yield to the College of Surgeons, but, by obtaining a separate incorporation, wait patiently, and the College of Surgeons would eventually be obliged to yield to us.

Mr. Stephen Ward, in seconding the resolution, read a portion of Mr. Guthrie's Manifesto. He said that many men were misled by party misrepresentation, cloaked by sophistical arguments. We have nothing now to hope for from the minority of the Council of the College of Surgeons. We could never form an alliance with men who have trampled on us in such a manner. By the New Bill, we can lose none of the privileges which we now enjoy as surgeons; and what are those privileges? The right possessed by the public generally of entering the College Museum and Library. Are these to be compared with the privileges to be expected in the future College? A College in which the aristocracy of mind and merit will rise,—a College with its Library, its Museum, and its Hall, in which its Members may meet and discuss all matters connected with the profession;—a College which shall, in a few years, rise to an equal rank with any scientific institution in the world! If we do not succeed, we have shown our spirit to the public, and we must know that the same kindred feeling has pervaded us all. (much applause.)

The Resolution was carried unanimously.

Mr. White proposed the fourth Resolution:—

"That, in the opinion of this meeting, it is most desirable that the Physic and Surgery Bill, with certain amendments, should be passed during the present session,—inasmuch as a postponement of the question would prolong a state of agitation and excitement entirely at variance with the habits and pursuits of medical men."

He spoke of the amendments in the present Bill, which was essentially a new measure, Sir James Graham had, in his opinion, acted with great fairness. He had taken extreme trouble to satisfy the profession generally. The General Practitioners had complained that they were not represented on the Council of Health, and now there were two members of that body to be elected on the Council. He considered this a very fair representation. With respect to the preliminary examination, he thought it better that General Practitioners should not be on that Board. All would have to pass it, whether Physician, Surgeon, or General Practitioner. He thought it would have the effect of increasing the amount of education required from the student, and consequently of elevating the general standard of the profession. The registration clause is also much improved, and will, in its effects, be compulsory. The Druggists complain that they will not be allowed even to prescribe in their own houses. Now it can never be the intention of the profession to carry out this provision to the strict letter. Another clause is also much amended—that relating to the striking off the name of any individual who may become amenable to the laws. As it at present stands such an individual may be again placed on the register on the recommendation of his college. With regard to Mr. Wakley, he thought they could not fairly consider him as a friend (groans and hisses) from the opposition he was making to the new measure.

Mr. Charles Jackson expressed his gratification at the prospect of peace being soon restored to the profession. They were essentially peaceful from the nature of their avocations. With regard to the clause complained of by the druggists, he was sure that no one would wish to carry it out to the strict letter; but it is quite necessary to prevent them from overstepping the bounds of decency and propriety in their practice, which at present they are in the habit constantly of doing. He concluded by seconding the resolution most cordially.—Carried unanimously.

Mr. Robert Wilson proposed the following—

"That the warmest thanks of the members of the Tower Hamlets Medical Association are due to the Committee of the National Association of General Practitioners in Medicine, Surgery, and Midwifery, for their disinterested, untiring, and persevering efforts to obtain for the General Practitioners an honourable and independent station in the Profession."

Seconded by Mr. James Jelf, and carried unanimously.

The Chairman then brought forward the following petition, which was signed by every member of the Association present:—

"*To the Honourable the Commons of Great Britain and Ireland, in Parliament assembled,*

"The petition of the undersigned General Practitioners in Medicine, Surgery, and Midwifery resident in the Tower Hamlets,

"Humbly sheweth—

"That your Petitioners have observed with great apprehension the postponement of the Bill for Regulating the Practice of Physic and Surgery; and your Petitioners earnestly entreat your Honourable House to take the Bill into your immediate consideration, in order that the dissensions and excitement which now so grievously agitate the Profession, may be terminated.

"Your Petitioners further pray, that if it should please your Honourable House to introduce any further amendments into the Bill, they be of such a nature as to grant to the General Practitioners the legitimate standing, rank, and title, to which by long usage and education, as well as by testimonials from the various Colleges, they have so indisputable a claim.

"And your Petitioners will ever pray."

A vote of thanks was then given to the treasurer and secretary, with great applause, which was responded to by the gentlemen in turn, with much good feeling. The same honour having been paid to the chairman, the meeting separated with considerable hope of success.

Our reporter was assured that the majority of the members of this Association are so disgusted with the conduct of the Editor of the *Lancet*, that those who were subscribers to that publication have now made it a point of principle to give it up.

We understand that Dr. Chambers have abandoned his intention of resigning the presidency of the Medical and Chirurgical Society—a change of intention which he has been led to adopt at the solicitation of a large number of the Fellows, by whom his wish to resign was received with exceeding regret.

The following gentlemen were admitted members of the Royal College of Surgeons on Friday, June 13th, 1845: H. A. Ebdon, J. Hoffman, S. Buchanan, W. Carroll, F. Burnham, C. E. Goodman, T. Maxwell, B. Longmore, J. Byrne, and T. M. Derry.

THE LIVERPOOL MEETING.

To the Editor of the Medical Times.

SIR,—May I request you will insert the following resolutions, which were passed at a public meeting of the Medical Practitioners of Liverpool and the neighbourhood.

The meeting was called by circular, shortly after the last statement of the College of Surgeons was made public, and was attended by about seventy gentlemen.

No other general meeting has been called since the Amended Bill has been brought out, so that it may be confidently stated, that the resolutions embody the opinions of the profession in this town.

Allow me, Sir, also to remark, that instead of *twenty* in this town having withdrawn their names from the National Association, as stated in the *Lancet* of June 7th, *seven* only have withdrawn since the first of May, and that a great many more joined.

I remain, Sir,
Your obedient servant,
THOMAS INMAN, M.D.L.
Secretary to the Meeting.

Medical Institution, Liverpool,
June 12th, 1845.

[Our crowded space, and the late arrival of the communication, allow us but to say, that the resolutions strongly approve of the Bill, and the conduct of the National Association. Similar resolutions should pour in from every quarter.—ED.]

To the Editor of the "Medical Times"

SIR,—If you think the accompanying case interesting, either in a medical or entomological sense, you will by inserting it in your valuable journal, oblige, Sir, your obedient servant,

J. W. MOSES, M.D. M.R.C.S.

St. Asaph

A few days ago, a lady showed me her hand, the palmar surface of which was studded with minute papulæ, and itched intolerably. The appearance presented was like the irritation produced by the spiculæ of the dolichos pruriens, or of the common nettle. On examination with a microscope, I discovered minute black hairs sticking in different portions of the skin. The removal of these, and the application of sweet oil soon caused the itching to subside. In explanation, the lady informed me, that whilst walking in the fields she was struck with the beauty of a large hairy caterpillar, which was crawling on the ground, and took it up, when the creature immediately coiled itself into a round form, after the manner of the echinus, and she suffered it to remain in her hand for some time, having a kid glove on of the usual thickness. The consequence was, as I have described; the larvæ had not only detached these little spines, but had forced them apparently through the kid glove and cuticle into the true skin. I examined the glove, from the inside of which numbers were protruding. Whether the insect possessed a voluntary power of discharging its spines, or they were detached by mere mechanical pressure, I cannot say; however, the muscles by which the different larvæ contract themselves are very powerful, as it is almost impossible to unfold them without injury, when corrugated. I regret not having been able to discover the distinct species of caterpillar in this case, but think, from the description given, that it belonged to the tenth order of insects—lepidoptera of Linneus.

BENZOLINE.—At a meeting of the Royal Society, a paper was read by Dr. Fownes on benzoline, a new organic salt-base, obtained from bitter almonds. Pure oil of bitter almonds is converted, by the action of a strong solution of ammonia, into a solid white substance, having a crystalline form, and which was termed by M. Laurent, hydro-benzamide. The author found that this substance by the further action of alkalies, became harder and less fusible than before, and not differing inchemical composition from the original substance, but exhibiting the properties of an organic salt-base. To this substance the author gives the name of benzoline. The salts which it forms by combination with the acids are, in general, remarkable for their sparing solubility, and many of them, as the hydrochlorate, the nitrate, and the sulphate, are crystallizable.

GOSSIP AND NEWS OF THE WEEK.

The Medical Bill that was to have come on on Thursday evening, has been postponed, with some others, to make way for a discussion on New Zealand.

The case of Wakley, M.P. against the *Medical Times* comes off this day (Friday) at the Exchequer Court, Westminster.

The following gentlemen were admitted licentiates of Apothecaries Hall on the 12th June, 1825:—John Pemberton, Francis Richard Gibbes, John Hey, George Pickess, Alfred Henry Bayley, Christopher Adcock, James Johnston Mitchell, Frederick John Hensley, and Matthew Baines.

THE GENERAL PRACTITIONERS OF LIVERPOOL.—A meeting of the members of the National Association of General Practitioners residing in this town was held on Monday last, in the Medical Institution, Hope-street, Mr. T. Blackburn in the chair, for the purpose of appointing a representative to proceed to the metropolis, in conjunction with upwards of ninety other deputies, from whom the Home Secretary, at his discretion, would select the forty-eight members who should constitute the first council of the New Royal College of General Practitioners, to be established under the right hon. baronet's medical bill. Mr. Harris, the secretary, seconded by Mr. Inman, nominated Mr. Minshull to the office; but, on a ballot, Mr. Rogerson, who was proposed by Mr. Swift and supported by Mr. Dawson, received a majority of two votes, his opponent having obtained six. Four gentlemen did not vote at all. Mr. Rogerson returned thanks for the confidence reposed in him, which, he said, amply repaid him for the obloquy he had received in his younger days while advocating reform. It was most gratifying to him, after the lapse of so many years, to find the principles he then put forth meet now with no opposition. Dr Watson then called attention to a statement in the *Lancet*, to the effect, that the Liverpool members of the National Association consisted of only twenty in number, and even they had withdrawn; and, at his request, the secretary, Mr. J. P. Harris, stated, that the minimum of enrolled members was sixty-five, and that none had withdrawn. After a little further conversation, Mr. Blackburn received the thanks of the meeting for his conduct in the chair, and the proceedings terminated.—*Liverpool Albion.*

HOUSE OF COMMONS.—The following orders, and notices of motion, were in the order paper fo Thursday, June 19: Physic and surgery bill—committee; colleges of physicians and surgeons bill—committee. 1. Mr. Muntz—to move, before the Speaker leaves the chair to go into committee upon the physic and surgery bill, that the committee be instructed to consider a clause obliging practitioners to write their prescriptions at full length in English, and chymists and druggists to have their jars, bottles, &c., labelled in English, in the same manner. 2. Mr. Wakley—to move, as an amendment on the reading of the order of the day for the re-commitment of the physic and surgery bill; that the further consideration of the bill be postponed until an enquiry has been instituted by this House into the circumstances which led to the granting of a new charter to the Council of the College of Surgeons of England in 1843; and into the effects produced by the operation of the provisions of that charter on the station and interests of many thousand members of that College: also, that it is not expedient nor just to incorporate the surgeons of England and Wales in any institution not possessing equal rights and privileges at law with the present Royal College of Surgeons of England. 3. Mr. Shaw—in committee on physic and surgery bill, to move an amendment.

A SELECT PRACTICAL FORMULARY.

TRANSLATED FROM THE FRENCH OF M. FOY, PRINCIPAL PHARMACIEN OF THE HOSPITAL SAINT LOUIS, AT PARIS.

(Continued from page 132.)

SYRUP OF TANNIN (Fiard): two ounces of tannin, one pint of water, two pounds of sugar, made into a syrup secundum artem. Mode of exhibition—a spoonful every four hours in cases of passive hæmorrhage.

——— VERMIFUGE (Bouillon Lagrange): two pounds of white sugar dissolved in a pint of the distilled and concentrated water of semen contra by means of a water-bath. Mode of exhibition—half an ounce to an ounce in the four and twenty hours. The same dose is repeated for several days, and a gentle laxative afterwards given.

SODA POWDERS: four drachms of powdered tartaric acid divided into twelve packets, and put up in white paper; six drachms of the bicarbonate of soda, divided into twelve packets, and put up in blue paper. Mode of exhibition—one of the packets of acid is dissolved in a large glass containing water, after which a packet of the alcaline salt is added, the whole stirred and drank at once. It is a cooling and slightly laxative drink.

SODA WATER: a gaseous water containing one grain of bicarbonate of soda in the ounce. Mode of exhibition during meal time, to assist digestion.

SODA, BICARBONATE OF: thirty to forty grains in bolus, pill, or solution, used as a diuretic in calculous affections dependant on an excess of uric acid. Three to six grains in acidity of the digestive apparatus, combined with bitters. It is also employed in the treatment of scrofula, and finally it is prescribed as an external application in some cutaneous affections.

SOLANINE: solanine is a powerful narcotic: it does not dilate the pupils; it paralyses the lower extremities, & Scarcely ever used.

SOLUTION OF THE ACETATE OF MORPHIA (Magendie): sixteen grains of the acetate of morphia, four drops of acetic acid, rubbed together in a glass mortar, and one ounce of distilled water and one drachm of rectified alcohol added. Mode of exhibition—five to twenty drops in a potion, julep, &c. Used as a succedaneum for laudanum.

SOLUTION OF THE ACETATE OF LEAD (Ricord): eight ounces of water, one drachm of crystallized acetate of lead. Used in injections in balanitis, and as a topical application for leech bites.

SOLUTION ALCOHOLIC OF THE DEUTO-IODURET OF MERCURY (Ricord): a solution containing twenty grains of the deuto-ioduret of mercury to the ounce and a half of alcohol at 36°. Mode of exhibition—ten to twenty drops and more progressively in a glassful of distilled water. It possesses the same properties as the proto-ioduret of mercury.

SOLUTION, ALCOHOLIC, OF CREOSOTE: a solution containing one ounce of creosote to the pound of rectified alcohol. Mode of exhibition: a small piece of cotton is dipped in this solution and introduced into a carious tooth; it soothes the most severe pain.

SOLUTION ALCOHOLIC OF CORROSIVE SUBLIMATE (Ricord): twenty to forty grains of the deuto-chloruret of mercury, one ounce of rectified alcohol, made into a solution. Used to cauterize indolent buboes.

SOLUTION, ANTI-EPILEPTIC (Magendie): four drachms of the ioduret of potassium, two grains of iodine, dissolved in three ounces of mint water and three ounces of orange flower water. Mode of exhibition—three spoonsful in the course of the day.

SOLUTION ANTI-PSORIC (Derheims): a solution containing three ounces of chloruret of lime to the pound of pure water. Mode of exhibition—used in lotions on the thighs, legs, and arms, two or three times a day. From six to eight days are generally sufficient to cure the itch.

SOLUTION OF OPIUM, AQUEOUS (Chaussier): a solution containing two ounces of picked opium to the pound of distilled water and thirty grammes of alcohol at 36. Mode of exhibition—sixteen to thirty six drops and more in an appropriate menstruum, either internally or externally, in the irritating cough which precedes hæmoptysis, affections of the chest, certain irritations or inflammations of the eyes, the pains or swellings of the breast following a blow, cancer of the breast, and affections of the uterus. In the treatment of this last named disease it is used in the form of injection or rather pledgets of lint are soaked in it, and introduced into the vagina as far as the fundus.

SOLUTION OF THE ARSENIATE OF AMMONIA (Hospital St. Louis): a solution containing eight grains of the arseniate of ammonia in two ounces of distilled water and four drachms of spirit of angelica. Mode of exhibition: twenty to forty drops in an appropriate menstruum in the treatment of inflammatory tetters, and other forms of the disease.

SOLUTION, ATROPHIC (Magendie): four drachms of the hydriodate of potash, one ounce of syrup of marsh mallow, rubbed together in a glass mortar and eight ounces of lettuce water, and two ounces of mint water gradually added. Mode of exhibition: a coffee spoonful evening and morning in hypertrophy of the heart with increased action.

SOLUTION OF BORAX (Hufeland): a solution containing one drachm of borax in twelve drachms of rose or plantain water. Mode of exhibition—in lotions to remove the yellow patches on the skin which are called hepatic furfuraceous tetters, &c. The parts are moistened with it two or three times a day, and allowed to dry without being wiped.

SOLUTION, SEDATIVE: a solution containing four grains of the hydrocyanate of potash in the ounce of distilled water. Used externally as a topical application in rheumatic pains of the joints in gout, &c. Compresses, with it are applied on the painful parts, and kept constantly moistened.

No. 301 **SUMMARY.** June 26.

CLINICAL LECTURES ON MEDICINE,

Delivered at the Meath Hospital,

By Robt. J. Graves, M.D., M.R.I.A., &c.

Gentlemen,—Since our last meeting, the patient Sarah O'Neil has died. You remember, that the tympanitis which came on during her fever, was relieved by intestinal hæmorrhage about the fourteenth day. I stated then, that critical hæmorrhages in fever very frequently precede a salutary change in the condition of the patient, and where they are not excessive or inordinately prolonged, are generally followed by a speedy convalescence. In this case however, owing to peculiar circumstances, it became a source of great apprehension; it continued for four days and nights, and induced a state of debility which threatened almost immediate dissolution; we therefore found it necessary to interfere with as much promptness and energy as possible. We prescribed the acetate of lead with opium in full doses, and allowed her the free use of port wine. By these means the hæmorrhage was checked, and the pulse which was as high as 200 fell to 120. She remained for two or three days in a very weak state, as it was natural to expect in a person who had lost so much blood, for in all cases of this kind when the powers of life have been reduced by the excessive quantity of the discharge, the danger is by no means over when the hæmorrhage has ceased. It is the same thing in cholera, where the loss of a vast quantity of serum from the stomach and bowels, induces such a state of debility, that the patient sinks even after our efforts in checking the diarrhœa and vomiting have completely succeeded; or, should he survive, he has still to encounter all the dangers which accompany the stage of reaction. And so it was with respect to this young woman's case; she recovered from the hæmorrhage, but was attacked shortly afterwards with inflammation of the bronchial mucous membrane, for which we blistered her chest, and prescribed the decoction of polygala with carbonate of ammonia. On the 4th of April, that is to say, three days after the cessation of the hæmorrhage, a new and important feature was added to her case. She had been for the two preceding days very feverish and restless, which was chiefly attributed to her bronchial affection, but on examining her chest on the morning of the fourth, we observed two or three large vesicles filled with a sero-purulent fluid, and on making further search we discovered others of a similar character on the arms and legs. From the circumstance of having observed a festering wound at the bend of the elbow, where she had been bled before her admission, I was at first inclined to look upon them as being vesicles, such as have been first noticed and described by Mr. Colles in certain cases of wounds of a malignant character. On second consideration, however, I was inclined to look upon them as varioloid. It appeared too, that a patient had been lately admitted into the same ward for an attack of fever, which afterwards turned out to be that of small pox.

The supervention of a new and important disease in her weak and debilitated condition rendered her case completely hopeless. Her pulse became weak and could scarcely be felt, the cough and distress of breathing increased, she lay entirely on her back, and seemed to take no notice of surrounding objects; and on the morning of the sixth she died with tracheal rattle after an illness of about twenty eight days. On examining the body, the mucous membrane of the lung was found thickened and vascular, and the bronchial tubes were filled with a secretion of a muco-purulent appearance. In various parts of the larynx and trachea, distinct varioloid vesicles were seen, indeed they could be traced to a considerable distance in the bronchial tubes. The viscera of the abdomen were sound, with the exception of the small intestine, which presented numerous ulcerated spots in the situation of the glands of Peyer. Some of them had clots of blood still adhering to their surfaces, and it is very probable that they were the chief source of the hæmorrhage. On examining the pharynx, several varioloid vesicles were discovered, and in different parts of the œsophagus those which had been broken, gave to the mucous membrane the appearance of having been touched at various points with a pencil of lunar caustic. None could be discovered below the inferior orifice of the œsophagus.

I may observe here, that the fever which appeared a few days before this young woman's death, was entirely connected with the attack of varioloid, and had no relation to the state of the intestinal tube. She had no diarrhœa; the abdominal swelling and tenderness had disappeared, and it is almost certain that had she not been attacked with fever a second time, her youth and good constitution would have enabled her to get over the ulceration of the mucous follicles. That a patient may recover from this state of the intestinal canal, is proved by the cicatrizations found in the intestines of those who have recovered from fever with symptoms of ulceration of the bowels, and afterwards died of some other disease. It cannot however be denied that this is a very dangerous state, and very frequently followed by a fatal termination. It may destroy life either by causing excessive diarrhœa, or by hæmorrhage, or by fever and gradual exhaustion, without any kind of intestinal flux, or by perforation of the coats of the bowel, and effusion of its contents into the cavity of the peritoneum.

I may observe that varioloid, when it attacks a person previously in good health, seldom produces any disagreeable or dangerous consequences. In some cases however it is accompanied at the commencement with high febrile excitement.

A person who has been properly vaccinated, may after the lapse of some years, on being exposed to the contagion of small pox, have an eruption ushered in by violent fever, thirst, restlessness, pain in the head and loins, and other symptoms of an alarming character. Indeed I do not know any fever which sets in with more violent symptoms than that which occasionally precedes an eruption of varioloid. I have seen many cases in which the determination to the head has been so great as to oblige me to have recourse to bloodletting, leeches, and other means, which in ordinary cases of the disease are wholly inadmissible. In the present case, the fever, owing to her debilitated condition, did not assume this intense character; it was however accompanied with considerable excitement, and most serious bronchial inflammation, and has been the cause of death.

It is thus that our best directed and most successful efforts are sometimes baffled by an unlucky train of events; this fine young woman fell a sacrifice not to one, but to the united effects of three diseases coming on one after the other. In the first place fever of a malignant character; secondly, hæmorrhage from the bowels, profuse and continued, from which she was only saved by the most energetic means, and saved after a degree of debility and a derangement of the circulation had supervened, which seemed to preclude all hopes. When just recovering she was overwhelmed by a violent attack of varioloid. I remember to have witnessed a family persecuted *to death* in a manner quite as persevering. First the children had measles severely; while convalescent, they were attacked by the violent influenza of 1832, and after that was over, were seized with hooping cough, which carried off all four!

A few words with respect to the case of Catharine Cowen, who was attacked with symptoms of fever on the 26th of February. Her fever commenced with rigor, pain in the head, noise in the ears, nausea, and vomiting. When admitted on the third of March, she was, in addition to her fever, labouring under an attack of erysipelas of the left side of the face. The cheek was covered with bullæ, the eye closed, and the ear red, tender, and swollen. She complained of headache, had not slept for two nights, and was extremely restless; but she had no delirium, and answered freely and distinctly when addressed. There was no affection of the intestinal tube; her respiration was rather easy, her pulse 96.

Here we find a violent erysipelatous attack setting in on the sixth day of fever, accompanied by headache, swelling of the face and external ear, but the patient's pulse was found to be soft, and not more than 96. Notwithstanding this I ordered her to be blooded, sitting up in bed. She had scarcely lost five ounces, when she became pale and fainted, so that it was necessary to tie up the arm. The blood did not separate completely into serum and crassamentum, but one half of the coagulum was found to consist of buff. I then ordered her to be leeched behind the ears, and to have the leeching repeated, in case the headache continued. In addition to this, I ordered the following mixture, of which she was to take a table spoonful every third hour. ℞ Infusi Sennæ ℥vss., Tincturæ Sennæ, ℥ss., Antimonii Tartarizat. gr.j. Electuarii Scammonii ʒss. M.

In cases of this kind, where erysipelas attacks young and robust persons, you commence by abstracting blood locally or generally, according to circumstances, and then if there be no manifest irritation of the digestive tube present, you pro-

ceed to the use of emeto-cathartics. After a few days, when the more violent symptoms are checked, you are to have recourse to diuretics combined with antimonials, and finally to diuretics combined with absorbents. In this way you remove the disease gradually but certainly, and without exposing the patient to any risk. Had I time, I could prove to you that we are authorised in this gradual progress from bleeding to emeto-cathartics, then to diaphoretics combined with cathartics, and lastly to a combination of diuretics and absorbents; it will be sufficient however, to mention at present, that this is the mode of treatment which experience has proved to be the most successful.

If the brain had been threatened in this case, a different mode of treatment would have been necessary. I may observe, that we are not to suppose in the present instance, that the headache and sleeplessness are indicative of cerebral inflammation. In erysipelas of the face and head, there is generally a great deal of irritation present, the patient complains of headache, nervous agitation, and restlessness; but where there is only slight headache, and a train of symptoms such as you have witnessed in this girl, you need not be apprehensive. But if symptoms of a decided affection of the brain were to appear, the most energetic measures must be immediately employed. Had this girl been thus threatened, I should have applied a large blister to the back of the neck, and dressed it with mercurial ointment, and given large doses of calomel so as to affect the system as rapidly as possible. In many cases of this kind, I have, odd as it may appear, combined the calomel with opium. In persons advanced in life, or of intemperate habits, where about the fifth or sixth day of erysipelas of the head, the patient lies sleepless, raving, and incoherent, but can answer questions when roused, I have given calomel and opium, both in full doses, with decided advantage. By this plan of treatment, a patient, whom I visited with Dr. Marsh and Dr. Corrigan a few months ago, was rescued from imminent danger. Perhaps no more difficult question can occur in practice, than when we shall give opium in erysipelas of the head?

The next case to which I shall call your attention is that of J. Duffy, a little boy who on the first of this month was attacked with symptoms of fever followed by thirst, nausea, and vomiting. On his admission six days afterwards, we found him complaining of headache and sleeplessness, but the fever, thirst, and abdominal symptoms had disappeared. The weight of the disease seemed to have fallen chiefly on the respiratory system, for he had loud, hard, incessant cough, increased by motion, and without any expectoration. The moment I heard the peculiar sound of the cough, and observed that it was increased by motion, a suspicion of the existence of pneumonia struck me, and on applying the stethoscope under the right scapula, I found extensive dulness, absence of the respiratory murmur, and crepitus. Over all the rest of the thorax, respiration appeared to be clear and natural, but here instead of the clear sound, we had nearly complete absence of respiration, with slight crepitus. The disease was therefore fever complicated with extensive inflammation of the postero-inferior part of the lung.

Now inflammation of the parenchyma of the lung, when it attacks children, presents some remarkable points of difference from the same disease in the adult.

I am not at present prepared to enter upon an explanation of the pathological differences which exist between the pneumonia of infants and children below the age of three, and children above that age; certain it is that important differences do exist, and that also inflammation of the lungs in adults is essentially different from both. Again, in persons advanced in years a fourth variety of pneumonia occurs, whose features are very characteristic and peculiar. Observe, Gentlemen, when I assert that inflammation of the lungs assumes different characters according to the age of the individual attacked, I am touching on a practical point of the greatest importance, for I have no hesitation in adding that the same mode of treatment is not applicable to any two or three varieties of pulmonary inflammation. Thus mercurial salivation rapidly produced is our sheet-anchor in the pneumonia of adults and persons in the vigour of life, but such a method of treatment cannot be applied either in infants, children, or in old persons. Again in the pneumonia of children above three years old, nauseating doses of tartar emetic, persevered in with judgment, and combined with blood letting, leeching, blistering, &c., are chiefly to be relied upon, whereas in infants a perseverance in the exhibition of tartar emetic for more than one or two doses is inadmissable, while minute doses of calomel, ipecacuanha and chalk, exert a most beneficial influence on the complaint. In infants too, there must be much more caution exercised with respect to the detraction of blood; but, Gentlemen, I find that this subject has not yet been examined with the attention it deserves, and that consequently we cannot yet lay down general rules for your guidance. Certain I am that much remains still to be done concerning the best means of treating inflammation of the lungs according to the age of the patient. A very good foundation for the pathology of this disease in infants and children has been laid down in an essay by Gerhard which you will find detailed in a former number of the Dublin Medical Journal.

In the case before us there were some circumstances worthy of remark, as being calculated to make a false impression, and to prevent us from following the only mode of treatment likely to produce relief. There was no febrile action present, and the pulse was only 72, soft and regular. There was scarcely any heat of skin, the bowels were natural, and he had some appetite; the only circumstances indicative of general disturbance of the system were some foulness of tongue and want of sleep. Here the state of the pulse and skin, with the absence of fever, would be likely to mislead the practitioner, and cause him to overlook the real nature of the disease. I need not tell you, gentlemen, that this would be a very important error; the spontaneous efforts of nature would be totally inadequate to its removal, and it would in all probability terminate fatally.

You may perhaps ask, whether the state of pulse, observed in this boy, be a good or bad sign. If we look to nosological arrangements, we shall find that pneumonia is generally accompanied by a strong quick pulse, in fact that this is its natural condition under such circumstances, and therefore we should say that the slow and tranquil state of the pulse in this case was not a good sign. But my impression is that, *cæteris paribus* the quieter the pulse in pneumonia, the better. It indicates a disease of less violence and much more amenable to treatment. The worst cases I have seen, all those cases of young and healthy individuals which terminated fatally in spite of active treatment, were cases characterized by high excitement of the circulation, and where bleeding, leeching, and tartar emetic failed in overcoming the hardness, or abating the velocity of the pulse. Thus in a case which I saw with Mr. M. Colles, and where the patient was a powerful strong man, bleeding after bleeding failed to diminish either the frequency or the hardness of the pulse, neither did the most energetic measures in the slightest degree seem to check or even retard the progress of the inflammation, which, producing a rapid hepatization of one portion of the lung after another, soon proved fatal: so great was the arterial action in this case, that all the superficial veins of the hand had a distinct pulsation communicated to them. On the contrary, when the pulse is soft and slow, the disease though likely to be latent, and thus give rise to error, is generally under the influence of ordinary treatment. Wherever the pulse remains quick and hard after the employment of free antiphlogistic treatment, your prognosis should always be doubtful if not unfavourable.

In treating this boy's case I did not order general bleeding, for no matter where the inflammation may be situated, if it has no effect on the general circulation, *if it be unaccompanied by increase of pulse and heat of skin, you may dispense with venesection*, for it will not do any good. Here your means of treatment should be cupping, leeches, blisters, and the internal use of antiphlogistic remedies. I have ordered this boy to be leeched and blistered, and to take small doses of mercury. I beg leave to observe here, that in exhibiting mercury for pneumonia in children, or boys under the age of puberty, I do not, as in the case of adults, prescribe it in large doses, or with the view of producing a decided action on the system. In the pneumonia of adults, calomel is given in very large doses (I sometimes give it in scruple doses twice a day), with the view of inducing sudden salivation, because we know from experience, that there is nothing which checks so rapidly the progress of inflammatory action. It is true that mercury will occasionally stop the further progress of pleuritis or pneumonia, without having affected the mouth, just as we now and then observe the removal of syphilis without actual salivation. But, generally speaking, when you give mercury to cure syphilitic iritis, common pneumonia, or pleuritis, its action is more favourable and more decidedly curative, when it operates fully on the system, as denoted by the affection of the breath, gums, and salivary glands. This however, is not the case with respect to children or boys under the age of puberty. Mercurialization has not the same beneficial influence on the pneumonia of early life, as at the adult period, and I believe the same remark will be found to hold good with respect to the aged. Certain it is, that in very young children and infants it is scarcely possible to affect the gums, mouth, and salivary glands, in fact to establish a true sore mouth and fetid breath by means of mercury; with respect to the aged, I cannot affirm positively, that the same observation applies, but this I know, that *large doses of mercury*, calomel for instance, do not cure inflammations in old people with any thing like the certainty they display in the inflammations of young adults, or of the middle aged. In the present case I have given calomel in small doses, combined with ipecacuanha. It is not my intention to carry it so far as to affect the system, and I have combined it with ipecacuanha, because its administration in this way has been found exceedingly useful in the bronchitis and pneumonia of children. We attempted here the resolution of the pneumonia by leeching, blistering, an antiphlogistic regimen, and the use of calomel and ipecacuanha, half a grain of the former and a quarter of a grain of the latter every fourth hour. This acted twice on the bowels, and it is very probable that this soluble state will continue. Yesterday I ordered eight leeches to the chest, and when the bleeding ceased, eight more were to be applied. To-day, I have ordered twelve more. When you apply leeches to the chest in children, you should not rest content with merely ordering them, you should know how they are applied. There is a vast difference between merely prescribing remedies and seeing them properly employed. It too often happens that this powerful means of checking inflammation, is rendered inefficient or even injurious by want of attention on the part of the physician. The leeches are ordered and sent from the apothecary's, but they are applied by an inexperienced mother or a bungling nurse. They are put on one after another any where they may chance to take, very seldom over the proper place, and during the whole time they remain on, the child's chest is left quite naked. This needless exposure of the chest is further increased by the habit of applying fomentations after the leeches have dropped off; the child gets fresh cold, and when the physician comes next day, he finds matters worse than before. The best way of applying them is to put them into a small box made of fresh deal shavings, such as is sometimes used for pillboxes, and place this exactly over the inflamed part. Having thus applied them over a circumscribed space, you may draw the bed-clothes gently over the child's chest, and he may remain covered until they are about to drop off. When they have dropped off, instead of fomentations, order a warm dry sheet or large piece of flannel to be placed over the chest, and in this way you will be able to get a large quantity of blood without exposing the child to the risk of cold. You may perhaps think these observations unimportant and even superfluous, but I am convinced that I have seen lives lost for want of proper care and expertness in the performance of an operation apparently so easy.

COURSE OF LECTURES ON THE THEORY AND PRACTICE OF MEDICINE.

Delivered by C. J. B. WILLIAMS, M.D., F.R.S., Professor of the Practice of Medicine, and of Clinical Medicine at University College.

The diagnosis of insanity has reference to its distinguishing characters from other affections of the mind. It is chiefly founded on the history of the case, as well as the existing state. The prior occurrence of a similar disorder of the mind would favour the idea that it was insanity. In the existing state, the absence of fever, or only a slight amount of fever would favour that idea; also the absence of intolerance of light and sound usual in acute affections of the brain. The delirium of phrenitis is more incoherent than insanity. The patient is less observant of things about him, and more engrossed with the delirium within. The pulse is less affected in insanity than in phrenitis, but phrenitis may occur in the first outbreaks of insanity. Delirium tremens is readily distinguished from insanity, the peculiar tremor that accompanies it, and by the occurrence of a remarkable clammy and profuse perspiration, by great weakness of the body, and weakness and frequency of the pulse. The tongue, too, in delirium tremens is covered with a thick moist, clammy film. The history of the case will generally serve to distinguish it, but it is difficult to say when real insanity begins. It imitates other disorders of the nervous system, and the sensorial functions, and to detect this we must refer to the history of the individual. We find some of the modifications of hysteria to have preceded this delirium, and that the delirium likewise has changed its character, and is alternated by these symptoms. Hysterical delirium is usually transient, and does not last. There is one kind of monomania that may bear a strong resemblance to hypochondriasis, though hypochondriasis differs in the existence of some definable bodily sensations, and in the absence of ideal things, such as monsters, &c. The distinguishing mark between melancholia and hypochondriasis is that, in the former the patient is reckless of himself, and this leads him to self-destruction, whereas in hypochondriasis there is the greatest anxiety in the patient about himself. It is much more difficult to distinguish monomania from eccentricity; in fact, it is only a greater degree of the same malady. What is eccentricity in one individual, and tolerated as such, would confine another individual to a mad-house, if the eccentricity were inconsistent with his previous life. All eccentricities are not considered to amount to madness, or to be such as to require restraint; generally speaking, so long as they do not appear to compromise the safety of the individual or his property, or that of others. There are many instances of persons having singular notions, who are not only at large, but are useful to society. It is where the eccentricity increases progressively, and the individual changes character from time to time, that he becomes dangerous; when an individual for the first time in his life begins to show an eccentricity not usual to him, though he need not be placed under restraint, he must not be left alone. The tendency to change in the character, constitutes an indication that the individual should be watched and taken care of.

There are certain lesions frequently occurring in the heads of insane persons. The bones of the cranium become thickened, and harder than usual; there is hypertrophy of the bone, increased density of the substance of the bone itself. In some instances the opposite condition has been presented. In one case one hemisphere of the brain was atrophied, the other being entire. Cruveilhier says that this caused complete hemiplegia in one side, but the intelligence was unaffected. There are several other cases of idiocy given by Cruveilhier, in which the convolutions of the brain were diminished in size, or absolutely wanting. All these states are connected with various defects of the mind. There are various irregularities or inequalities found in the skull besides thickness: inequality of shape, want of correspondence between the two sides, but it is quite absurd to suppose that these different diseases of the bone are the causes; they are probably the consequences of changes taking place in the soft parts. In some cases the membrane—the pia mater—is injected, thickened, and sometimes infiltrated with serum; the surface of the brain is soft, and adherent to the pia mater; the cortical substance exhibits changes in colour, being of a yellowish brownish tinge; the medullary portion likewise exhibits changes of colour, and sometimes there is more or less softening, affecting the whole substance, but more frequently induration. Hardening is more usually the result of the chronic disease; softening, of the acute. Serum is found in the ventricles in various quantities, portions of them being variously enlarged. The disease chiefly affects the cortical substance. The medulla oblongata is rarely affected. In cases of recent mania, slight inflammation may be found. Foville, who has paid more attention to this subject than other pathologists, has come to the conclusion, that the cortical substance of the brain is the chief seat of the lesion in mental disorders, just as the medullary substance is the chief seat of the lesion where the motor power is disordered. In acute cases the cortical substance is different in colour, or altogether redder, or else it exhibits spots and patches of redness increased or darker; with this there is often softening of the cortical substance in different degrees in different persons. The cortical substance consists of a series of layers, and in many cases the external layers of the cortical substance are hardened, whilst that underneath is softened, or sometimes the converse, so that these different layers can be peeled one off the other in a manner not usual in the common condition of the brain. These layers can be seen distinctly in the healthy state of the brain, but they become more marked and distinct in disease. There is, too, commonly connected with this in the acute form, dilatation of the vessels; the arteries, particularly, are larger than usual, and their coats more resistant. In the more chronic affections there are found adhesions between the outer layer of the brain and the pia mater; and sometimes to the other membranes. In some cases, in the advanced stage, the external layer is paler than the cortical substance under it, that underneath being redder and softer, and sometimes granulated, presenting irregularities, instead of a smooth surface. Sometimes the convolutions are diminished in size, and thinner than usual. Sometimes they are rough and more granulated on the surface, or else pitted with small depressions, containing little cells filled with serum; and as there is never any thinning of the convolutions without there being necessarily some substance to occupy the place of it in the skull, this only corresponds with some effusion of serum on the outside of the membranes, or along the sutures of the ventricles. But all these changes, you observe, are confined to the cortical substance. In some cases there is more softening of the lower layers, and this occasionally extends to the medullary structure. The cortical portion presents various changes that may be ascribed to increased vascular action; a modification of nutrition—atrophy, hypertrophy and so forth. The medullary substance exhibits changes; increased injection, slight violet tints, more than in the chronic cases; greater opacity than usual, and an increase of the substance. Foville supposes this to arise from adhesion of the fibres of which this part of the cerebral matter is composed, while in the healthy subject these fibres are separable. In all maniacal subjects where this induration exists, the fibres are not separable, and therefore it may be inferred there is a deposition of new matter causing the adhesion of these portions together. These changes are connected with paralysis. In a few cases there has been found disease of the nerves in connection with hallucination, and if this could be established to be always the case, it would go far to establish its causes.

In applying these different results to explain the phenomena of insanity, we must take care to guard against supposing these lesions to be necessarily the causes of insanity, or that they are always essentially the source of the mischief. These changes are pretty clearly traceable to various effects of inflammation; these modifications are exceedingly analogous to those which inflammation produces in the brain and elsewhere. But it must be remembered that inflammation may be the consequence of continual maniacal excitement; we find that the other causes of functional disorder produce excitement, and that functional excitement precedes increased vascularity; and there is no reason to doubt that the brain, as well as the other organs of the body may become the subject of functional disorder, independently of any permanent lesion. There may be functional disorder of the three kinds I have formerly adverted to under the head of general pathology—excess, defect, or perversion. Excess of the mental powers, or the feelings, impulses, or faculties; defect of these or loss of balance, in undue proportion; and these functional disorders may arise either from mental or physical causes. It may be owing to the same circumstances that the mind, or the organ of the mind has become unduly excited, either in connection with congenital malformation, or a conformation acquired with the growth; some propensity or faculty acquires an undue development or an insufficient development, and this gives a predisposition to insanity. So, likewise, the mental powers may have the same loss of balance, the same predisposition to disease. This view is countenanced by the analogy of other organs and faculties, and the influence may be expressed through the vascular system, or through those causes of excitement which prove the immediate cause of the activity of the organs. We can readily see that functional disorder of the brain may disturb the circulation, without there being any physical disease; and it is perfectly reasonable to suppose that the functional irritation, or irregularity connected with the change in the circulation, cannot continue long in a structure so delicate as that of the brain without leading to some change, and generally in proportion as this takes place, the disease passes from functional irritation to permanent structural disease. There are many cases that seem to prove that increased excitement accompanies the development of insanity. The symptoms are beating of the heart, flushing of the face, heat in the head, partial or general; and this will, especially in the acute form, point out the determination of blood to the head. The manner, too, in which other bodily ailments will increase insanity seems to point out the same thing: the manner in which cutaneous eruptions, discharges of various kinds, and ulcers, become suppressed, seems to point out increased vascular action; and when these are restored, the symptoms of insanity are removed. You often hear of oddity and eccentricity in some member of a family, which becomes exaggerated into madness, and where the case is more partial, it is more hopeless because it is less under the control of medicine. It is probably more dependant on constitutional conformation, a peculiar temperament or habit, probably an undue development of nervous structure, or undue determination of blood with regard to some parts of the brain.

Thus leads to the treatment of insanity, which is properly divided into physical and moral. The physical usually has relation to those material influences on the function and structure of the brain; and the moral includes the regulation of the mental diet or regimen as it may be called. Seeing that lunacy or madness in every form is commonly combined with increased vascular action, it is not surprising that antiphlogistic measures should be long in vogue, and no doubt the evidence on the whole is very much in favour of these means of treatment, more particularly in recent cases, and in exacerbations accompanied by increased vascular action. Some physicians have bled to a great extent. Dr. Pritchard recommends moderate depletion in plethoric subjects; cupping and leeches to the head, or to the temples in recent cases, varying the amount according to the effect, combined with internal medicines to control the circulation. When once the determination gets to the head it seems to be fixed to the brain, and then it cannot be reduced without a greater amount of depletion. In these cases I have seen cupping and leeching fail, and in

one severe case they had no effect until the temporal artery was divided, and a few ounces of blood drawn. When we may not use depletion by withdrawing blood directly from the head, then venesection or leeches should be had recourse to. Much may be done by that. Cold applied to the head, and heat to the body is likewise found to be very useful. In France they keep the patients in a warm bed for several hours, and apply the cold douche to the head, two or three times a day. This is a very useful adjunct to blood-letting. Emetics have been recommended to reduce the circulation, but the effect of these have not been sufficiently distinguished, as emetics are only useful in cases of disordered stomach. But tartar emetic acts in a far more extensive way than upon the stomach only; and it is a very powerful agent in cases of great excitement, subduing the tension of the vascular system, and reducing the tendency to determination of blood. With the same object in view the rotatory motion of the swing which acts by a centrifugal power to draw the blood from the head has been used. The bath also has been applied in chronic cases, but those persons who have written on the subject are very doubtful as to its efficacy. Purgatives are always to some extent required; croton oil, and so forth.

In many cases of insanity we find antiphlogistic measures of only partial use, or even sometimes of no use at all. The condition of the system is, in these cases, usually that of weakness; there may be considerable vascular irritability—a disposition to partial determination of blood, or partial congestion; but no fulness, no permanent vascular action. In some cases the treatment should be that applicable to cases of anemia, the chief object being to allay the irritability by sedatives and narcotics; opium or morphia, in full doses, is the best. The great object in those cases, in which there is great nervous excitement, combined with a great deal of weakness, is to procure rest from the continued excitement that exhausts the system. The use of narcotics must be made conditional on the state of the vascular system, and they are not safe, and, indeed, are hurtful, so long as the pulse is hard, and the skin hot; but when these have been reduced by depletion, or when they are, in the first instance, not present, and when mental irritation exists to a great degree, narcotics are the leading treatment in the acute form of insanity. In those cases where the patient gets excited and restless, opium will often procure sleep, and when that takes place, a temporary cure is actually effected. When the disease is of a chronic character, these measures are not to be used without great discretion, and are only to be resorted to in cases of aggravation. The diet should be varied, and inflammatory action kept under. There are some cases of exhaustion, in which it is proper to adopt measures to compel the patient to take nourishment.

Periodical blood-letting is useful; with regard to counter-irritation there is some difference of opinion; many say that blisters and issues do more harm than good, and I cannot bear testimony to their efficacy from my own experience. The secretions should be attended to; watch the state of the urine, and use the proper remedies. In chronic cases it is of great importance to direct regular exercise in the open air, and to improve the condition of the system as much as possible in connexion with whatever treatment may be necessary to be directed to the head. The earlier the treatment is applied, the more chance there is of success.

With regard to the moral treatment—to try to reason persons out of their madness, or to punish them, has the effect of making them ten times worse, because it leads them to think on that which obviously should be kept away from their thoughts. It has been recommended to humour the patients out of their notions. Esquirol mentions the case of a person who imagined he had a serpent in his stomach, and his attendants were recommended to give him a powerful emetic, and then show him the serpent supposed to have been brought up. This kind of treatment seems to have been successful. The most important element in the moral treatment of insanity is to direct the thoughts and attention from the maddening subjects, to draw off the attention altogether, and to fix it on other matters; hence the great propriety of early removing the mad patient from the scene, or from the society where his madness commenced. This is of the greatest importance with regard to the commencement of insanity. It is of great importance to place the individual in an entirely new situation, so that all old associations, and all those associations which suggest the cause of the insanity, should be removed; there should not be more restraint than is necessary for the protection of the individual, and, in order to draw off the mind to other subjects in a gentle and pleasing way, every kindness, every amusement, every circumstance that can give pleasure, should be resorted to. Light mental occupations are always of great advantage. It is a very difficult thing to fix the attention of a mad person on anything, but frequently when the mind itself cannot be engrossed, the bodily attention can be attracted, and then the mind is employed in connexion with the body, and is prevented from dwelling on its thoughts. Now, in slight cases, where there is a tendency to oddity, driving about from place to place will often answer; but, generally speaking, a well conducted asylum is the best for the patient, where he will be entirely separated from his friends, and be altogether among strangers. With regard to restraint, all that is necessary is a strait waistcoat, to prevent the patient's injuring himself or others. The punishments should consist of slight moral punishment, such as children are visited with, debarring the patient from some amusement, or keeping him in a solitary room for a time. There is no question that the best means of leading mad persons, is that of drawing out their best affections, and avoiding excitement or irritation of any kind.

LECTURES ON THE PHYSIOLOGY AND DISEASES OF THE BRAIN,

By J. Bouillaud, D.M.P., M.,A.M.,

Member of the Chamber of Deputies, Professor of Clinical Medicine at the University of Paris, Knight of the Legion of Honor, Physician to the Hospital de la Charité, &c. &c.

LECTURE II.

Various, and often contradictory opinions, have been promulgated as to the functions of the cerebellum, which, however, were but little known, until the investigations of experimental physiology established the fact, that it is not endowed with sensation properly so called, and that if, in diseases of that organ, more or less intense cephalalgia is manifested, this phenomenon ought to be attributed to the sympathetic action exercised on the neighbouring nerves, rather than to the abnormal development of sensation, which does not exist in its natural condition. This opinion, to which Dr. Longet gives the authority of his name, was announced first by Bichat. As to the influence of the cerebellum on the organs of the senses and the intellectual phenomena, it has none.

Dr. Flourens was the first who performed conclusive experiments, and who located in the cerebellum, the power by which the different movements are regulated. I have also studied this question and performed numerous experiments, and I have been led to the conclusion, that the power is not so considerable as Dr. Flourens supposed, since the organ appears only to have an influence on the regulation of the powers by which locomotion is produced. Whenever the cerebellum is wounded in animals, disorder of the movements is produced, and it is extraordinary, that the agitation and disturbance in these movements are such, that the animal staggers like a drunken man. If the organ is irritated somewhat more severely, without, however, being completely destroyed, symptoms are produced in every respect similar to those of epilepsy, and, in some cases, the mouth is filled with water.* Where the greater portion of the cerebellum was destroyed by cauterization—which is preferable, because it does not cause hæmorrhage—the animals were incapable of preserving their equilibrium, or of walking without falling. However, all the movements are not irregular when the cerebellum is destroyed, for instance, the circulation, respiration, and deglutition—in a word, all the instinctive movements are performed with perfect regularity and precision. It is therefore evident that Dr. Flourens exaggerated the influence of the cerebellum, in considering it as the regulator of *all* movement, whereas, in reality, as has been already stated, it ought only to be considered as the regulator of the movements of locomotion; *i. e.* those of the organs by which the animal is able to convey itself from one spot to another, to stand, &c., and of all the various modifications to which these movements are susceptible.

To resume, Rolandi and Reil placed the source of all motion in the cerebellum, and stated that this organ acted on locomotion, in a manner similar to that of the voltaic pile. According to Dr. Flourens, it is only the regulator, whilst in my opinion it is the seat, of the faculty which all animals possess of remaining in equilibrium, and performing the various acts of locomotion; besides which, I have already shown, in my *Treatise on Encephalitis*, that the brain regulates certain movements.*

But has the cerebellum this function only? Is it not the seat of physical love, as Gall affirmed? This fact is far from being demonstrated, notwithstanding that the arguments presented by Gall in favour of his hypothesis, are, it must be confessed, in accordance with sound observation. But this distinguished observer neglected a circumstance of great importance if we wish to attain a correct knowledge of this subject: I mean experiments on living animals. For my part, while Gall was still alive I disputed this part of his doctrine, and since then I must add that nothing I have observed since my first researches authorize me to come to a different conclusion. Clinical facts tend rather to invalidate than to confirm the physiological experiments; there, however, remains much to be done on this head. What is positive with respect to the opinion announced by Gall, is, that individuals whose nucha is largely developed, are much addicted to venery, and that the bulls and stallions which are most ardent, are those, in which this part is largest. This opinion, however, can have but little weight, since the cerebellum is not the only organ which corresponds to this portion of the cranium. Moreover the cases in which erection and even ejaculation occurred during diseases of the cerebellum, are far from being conclusive, as these phenomena ought to be completely abolished, if the cerebellum really presided over the generative functions. But must it therefore be concluded that the cerebellum has no influence whatever? Certainly no one in the present state of medical knowledge would affirm positively that this was the case: it may be that a limited portion only of the cerebellum presides over these functions, but it would be extraordinary, nay more, it would be highly improbable that so considerable an organ should be destined to govern a single order of phenomena, common to all animals, such as generation.

Again, are the functions of locomotion and progression really under the influence of the cerebellum, or is only a portion destined to regulate the various locomotive movements while another, as Gall asserted, is appointed to preside over venereal desires and the phenomena of generation?

---

* Professor Bouillaud performed several experiments before his pupils; the lobes of the cerebellum of a pigeon were cauterized; the bird staggered as if tipsy; after some difficulty it succeeded in regaining its equilibrium, but after a short time, further efforts were necessary to preserve it. In a second pigeon, when cauterization was performed more deeply, the bird was incapable of remaining upright, it was violently agitated, fell on its back, &c., in short, at one moment it offered very irregular movements, whilst at another they ceased, or were similar to those observed during an attack of epilepsy.

* *Traité Clinique et Physiologique de l'encephalite ou inflammation du cerveau et de ses suites, telles que le ramollissement, la suppuration, les abces, les tubercules, le squirrhe, le cancer, &c., Paris, 1828, 8vo.*

Nay more, do not parts of this organ preside over other functions? It is impossible to give a positive answer to these inquiries, and indeed until clinical facts and experiments on animals solve the question, there is no reason why it should be concluded, that the opinion I have just stated is not correct, since nothing demonstrates positively that the cerebellum is the seat of physical love.

The next question to which attention must be directed, is the study of the functions of the brain. This organ is composed of different parts; of which the most important are the cerebral lobes, the corpora striata, and the thalami nervorum opticorum. Saucerotte thought that the corpora striata, on account of their fibres crossing each other in an antero-posterior direction, presided over the movements of the inferior extremities. This opinion was also supported by Drs. Foville, Pinel, and Grandchamp, who had opportunities of observing some pathological facts which seemed to confirm it, and by Dr. Serres, who stated that in his experiments on animals, he constantly met with this result. This *cross action* shows itself on either side; thus if the right corpus striatum is destroyed in an experiment, or by a pathological lesion, the left inferior extremity ought to be paralysed. In one of my works, on the affinity which exists between the movements of the limbs and the cerebral lesions, I published an opinion that in man the corpora striata appear to exercise an influence on the movements of the inferior extremities; however, I wish it to be clearly understood that I do not attach to this opinion greater importance than it deserves. Dr. Magendie has likewise put forth an opinion relative to the functions over which the corpora striata preside. This distinguished physiologist located in these bodies a power which would cause the animal to recede against his will, the cerebellum being the seat of the contrary power; therefore if the former were removed, the action of the latter being no longer counterbalanced, the animal would rush forwards with great rapidity. But Dr. Magendie soon changed his opinion, and Drs. Laffargue and Longet have proved by later experiments, that the influence of the corpora striata on the lower limbs is very slight, that animals after their removal are never irresistibly drawn forwards, unless during the experiment the optic nerves and some sensitive parts are divided, as then, being suddenly deprived of light, they become very much alarmed. Finally, psychologists are far from being decided as to the precise functions of the corpora striata. As to the opinion of Willis who placed in it the centre of all motion and sensation, it is still more erroneous than the preceding.

The functions of the thalami nervorum opticorum are likewise still enveloped in doubt; it appears however, evident, that notwithstanding their appellation, they have no influence on the sense of vision, this being situated in the *nates*, as was before stated. They may, perhaps, be considered as the centre of locomotion, exercising their powers cross-ways, as is proved by my experiments and those of Dr. Longet, rather than presiding over the movements of the thoracic extremities in opposition to the functions attributed to the corpora striata by Saucerotte, Foville, Pinel, Grandchamp, and Serres. These authors have sought to base their opinions on some facts which I consider far from being conclusive. As to the results furnished by vivisections and pathological anatomy, they are not in accordance; thus, whilst a pathological lesion—hæmorrhage for instance—causes paralysis, vivisection occasions, in the generality of cases, what is observed when the crura cerebri are divided, viz.—a circuitous movement (*mouvement de menage*) of the limb on the opposite side; besides, in the animals in which this phenomenon occurred, Dr. Longet never remarked that the anterior extremities were weaker than the posterior. Finally, it may be affirmed that the thalami nervorum opticorum are insensible to the action of irritating substances, since their fibres may be torn without any muscular contraction taking place, and without the animal appearing to suffer pain.

THE STRUCTURE AND FUNCTIONS OF THE BRAIN, WITH NEW VIEWS ON THE NATURE, CAUSES, AND TREATMENT OF MENTAL DISEASES.

By M. PINEL, M.D., Member of the Academy of Medicine,

Formerly Physician to the Bicetre and Salpetriere Asylums: Author of the "Traite Medico-Philosophique sur l'Alienation mentale" "Medicine Clinique," "Monographie Philosophique," &c., &c.,
Translated with Notes illustrative of some important doctrines in Physiology, Phrenology and Moral Education.

By Dr. COSTELLO,

Principal of Wyke House Asylum, Editor of the Cyclopædia of Practical Surgery, &c.

(Continued from page 37.)

I find in my father's notes, a case drawn up by Esquirol, which under the title of *paralytic dementia and stupor*, furnishes a striking example of cerebral œdema complicated with paralysis. It is here transcribed.

CASE V. A woman named Secointe aged 55, was admitted into the Salpetriere on the 20th September, 1811, in the state of dementia, stupor and paralysis. Lymphatic temperament, menstruation regular, kind disposition, but timid. Married at 22, she gave birth to a child in the following year. She had an attack of delirium that lasted two months, which yielded at the same time that her legs became œdematous. She was again delivered of two children, one in her 26th, and the other in her 29th year.

In her 36th year, she was so frightened by the explosion of the gunpowder magazine of Grenelle, that she was suddenly attacked with numbness in the left leg, and a gradually increasing difficulty of walking. In her 40th year, she was delivered of a still born child. In her 46th year menstruation ceased, and violent delirium supervened, during which she uttered cries, and found fault with every body. In her 53rd year after having passed a few weeks in the hospital of La Pitie, she was transferred on the 20th September, 1811, to the Salpetriere. At this time, she had lost the use of her limbs; her words were incoherent, and her evacuations involuntary. She was in a state of complete stupor and insensibility, and a large eschar was beginning to form on the sacrum. She died on the 30th March, Comatose.

Autopsy.—Skull thick, dura mater strongly adherent. Albuminous effusion under the arachnoid, abundant serum between the sulci of the convolutions.

Ventricles.—The lining membrane presents lenticular stains of a dirty white, depressed, and resembling the depressions which might be made with the thumb. On lifting up the membrane covering these spots, the white substance shows brown spots of the same form, and of a depth of two lines. The white substance closely resembles lard in some places, and muddy jelly in others. The surrounding substance is much denser, and resists the scalpel, allowing itself, like membraniform substance, to be torn rather than cut. One of the testes very much altered and thickened. Similar stains are observed in the fourth ventricle. The other viscera healthy.

This case of Esquirol's, observed as far back as 1811, is remarkable in many respects. In the first place, it describes an alteration, which was unknown up to the time of the interesting researches of Riobe and Rochoux, namely, the false membrane that is developed in lesions of the substance of the brain around the altered focus. This process of cicatrization, which Rochoux has so clearly pointed out in the absorption of apoplectic foci, is here applied to another kind of alteration. The same characters of these gelatinous or lardaceous-looking cysts are found in partial softenings of the cerebral pulp; they are distinguished from the apoplectic cysts by their not having those minute yellow cicatrices, or calcareous deposits that are always found in various degrees, in sanguineous effusions of long standing.

As regards the abundant serum, which, as Esquirol observes, penetrates into the furrows of the convolutions, I attribute to it the symptoms of stupor observed in this patient.

Finally, we may remark that the alteration of the right ventricle is more profound than that of the left, and that we have here a perfect relation between the symptoms of numbness and paralysis, affecting the left leg after the fright she had in her 36th year.

To these I have now to subjoin the interesting cases of Dr. Etoc Demazy; their details tend to confirm the new points which we are now considering.

CASE VII.—B., a sempstress, aged 30, of weak constitution and lymphatic temperament, was sent to the insane ward 11th October, 1832. She had been in a state of extreme debility and depression, accompanied even with typhoid symptoms. On the 15th November, the symptoms were as follows:—lies on her back; the legs cannot support her erect; she seems neither to hear nor see; the eyes are fixed; the skin dry and rough; the general sensibility, taste, smell, and sensation of hunger, appear to be completely abolished. She is supported by soup. The tongue moist, rose-coloured; evacuations involuntary; pulse soft, feeble, fifty pulsations a minute. The menstruation suppressed from the beginning of the attack.

She continued in this state till the 10th January, when diarrhœa supervened; the emaciation increased, and death took place on the 22nd.

AUTOPSY—EXTERIOR—CADAVERIC RIGIDITY—COMPLETE MARASM—SLIGHT EXCORIATIONS ON THE SACRUM.

Head.—The bones of the skull thin, easily broken; dura mater white, stretched on the hemispheres. The cerebral convolutions bulge out through the incision; arachnoid slightly opaque and thickened at the vertex. Pia mater thin, pale rose colour; its vessels appear atrophied.

Brain.—Convolutions large, pressed close together. Grey and white substance of the hemispheres moist, both infiltrated with serum. The œdema is greater at the vertex than at the base; at the bottom of each incision, whitish filaments are observed to pass from one side to the other of the divided surfaces. The ventricles contain about a spoonful of serum; a small oval cavity filled with serum exists in the right optic tract, no larger than a grain of wheat. The other parts of the brain healthy.

Thorax and Abdomen.—Nothing to be remarked beyond the greyness of the mucous membrane, and some small red spots near the ileo-cœcal valve. The walls of the uterus contain a fibrous tumour of the size of a walnut.

CASE VIII.—L., a sempstress, of a light, careless, and happy disposition. Her grandfather died insane. During the last four years she has experienced the most violent sexual desires. At the age of fifteen, she had several attacks of hæmoptysis, which were cured by numerous and copious bleedings. These evacuations were followed by a partial loss of sensibility, and such extreme weakness, as to render her unable to work. Indifferent to every thing, she seemed incapable of feeling either pleasure or pain. Five months afterwards, her gaiety and natural buoyancy returned; but the weakness remained.

At the age of seventeen, a physician applied no less than 200 leeches to the epigastrium, to combat an attack of gastro-enteritis; the leech-bites gave her no pain.

On the 21st December, 1832, without any known cause, she was found running about the streets, declaiming; she was taken up by the police, and sent to the Salpetriere. On her admission, her loquacity was continual, "*she was the sister of Napoleon!—she was to die on Good Friday, and to rise again on Easter Sunday; she was the owner of Valenciennes and all Belgium; she hears, sees, and speaks, with ideal persons—the walls are inscribed with characters of blood, &c. &c.*" She is of a nervous lymphatic temperament, and a broken-down constitution.

The general sensibility presents a remarkable phenomenon, being very acute on the scalp, as shown by the pain caused by pulling her hair; in the face; in the middle of the back along the spinous processes; on the breasts and sternum. While it was completely abolished in the nucha, the entire region of the ribs, abdomen, nates, and upper and lower limbs. The patient herself would force large pins into the pulp of the fingers without feeling any thing. The limits of the sensibility were not well defined. Due precautions were taken on this point to prevent any

deception on her part. The taste and smell were natural; the sensation of hunger and of thirst were urgent; the natural calls were also felt.

At the commencement of March, the hallucinations were the same; the delirium continued, though somewhat more calm; the intellect is becoming evidently weaker; the patient, hitherto so restless, becomes quiet, remains in bed or in a sitting posture; her features become more and more altered, from day to day, and she only utters slowly a few incoherent words. An abscess has formed under the jaw, giving issue to a thin, ill-conditioned pus. She has gradually fallen into a state of complete helplessness; she neither can see nor hear; the pupils are contracted, almost motionless; the pulse slow, incompressible, and varying from forty to fifty pulsations in a minute. Diarrhea, involuntary stools came on, the sacrum became excoriated, and she died in a state of marasm, on the 3rd of May.

AUTOPSY — EXTERIOR — CADAVERIC RIGIDITY — GENERAL PALENESS OF THE SKIN — SLIGHT EXCORIATIONS ON THE SACRUM, AND LARGE TROCHANTERS.

Head.—The base of the skull remarkably large. The integuments contain but little blood. The brain fills the skull completely, and the dura mater seems streched on the convolutions.

Meninges.—At the vertex, the arachnoid opaque, thickened in places; no serum between it and the pia mater, which is of a rosy hue, very thin, and free from any adhesion with the cortical substance. The convolutions larger at their summits are flattened and seem crowded against each other.

Brain.—The cerebral hemispheres cut into, are pale, moist, impregnated with a clear colourless serum; the infiltration is more marked in the cortical substance, which by measurement is four lines thick. The lateral ventricles contain about two tablespoonsful of serum; their walls are of a dead white, but of the natural consistence. The rest in the normal state.

Cerebellum.—Infiltrated in the same way as the cerebral lobes; the uniform layer that covers the surface is very remarkable. The rest is normal, except that the arched fasciculi are unusually developed; the sinuses of the dura mater empty.

Thorax.—Nothing remarkable in the bronchi, pleuræ, or lungs. The heart of the ordinary size and consistence, is covered in front by a yellow, soft, false membrane, a line thick, that unites it loosely to the pericardium; there are some coloured patches on its serous surface. The inner surface of the pericardium is also lined with false membrane, red and highly injected.

Abdomen.—The mucous membrane of the intestines is remarkably pale throughout, and so thin in a few turns of the small intestine, that this seems to be formed almost solely of the peritoneum.

CASE IX.—L——, a woman aged 27, recently delivered of a child, was attacked at the end of April 1663, during the period of the milk-fever, with delirium and violent agitation. Forty leeches to the epigastrium relieved the latter, but the delirium continued. This apparent quietude progressed daily until she fell into a state of extreme debility, and moral nullity. She was taken to the Salpêtriere on the 28th May. No information could be obtained as to the moral circumstances preceding the attack.

The patient is of lymphatic temperament and feeble constitution; the expression of her countenance is idiotic; the eyes fixed, dull; the pupils contracted; she seems not to see, hear, or feel; tongue moist, large, and of natural colour; evacuations involuntary; pulse small and feeble, 48 pulsations per minute.

Suddenly on 1st June, coma supervened with relaxation of the limbs, and pallor of the face without deviation of the mouth. Death four hours after.

Autopsy. Exterior. — Articulations supple. Laceration of the perineum.

Head.—Several ounces of black blood poured from the incisions of the scalp; dura mater stretched on the hemispheres; longitudinal sinuses large, filled with a fibrinous concretion; other sinuses empty. Arachnoid thin and transparent; pia mater rose colour, free from adhesion with the cortical substance. Convolutions large and flattened at their summits.

The hemispheres cut into were infiltrated with limpid serum which oozed out in small drops on pressure; they were pale, and presented only a few dark red spots. In the middle of the right one, an inch from the longitudinal sinus, the white substance contained a perfectly spherical, black blood-clot, of the size of a cherry, without any admixture of cerebral matter. The substance surrounding it was of a dead white, and softened like pap to the depth of two lines. This mass was removed with perfect ease by means of the scalpel, and was covered with the softened white pulp. Another blood clot, not quite so large was found exactly in the same circumstances at the corresponding point in the left hemisphere.

The lateral ventricles contained two spoonsful of limpid serum. The inferior surface was dotted with miliary granulations, similar to those met so often in the fourth ventricle of the insane that die paralytic.

Slight hypertrophy, with dilatation of the aortic ventricle. The mucous membrane of the alimentary canal slightly wrinkled and white, but of a healthy appearance throughout. The uterus had not regained its ordinary size and consistence.

These four cases, taken from M. Damasy's theses, present in a clear light the serous infiltration of the brain: the last being one of those rare instances in which œdema is complicated with cerebral hæmorrhage. We might be surprised at so small an effusion of blood producing so suddenly a fatal termination, did we not recollect that it occurred in a patient already greatly enfeebled and reduced.

We see from all these cases, that there is a remarkable coincidence between the œdema and serous infiltration that occur on the surface, as well as in the interior of the brain, and the production of certain symptoms of insanity, which we have designated by the name of the stupor of the insane. We may then admit, with some degree of certitude, the relation of the cause to the effect, and assign, as the organic cause of the disease, the cerebral œdema just described. We may advance to more precise details.

GENERAL ANATOMY OF CEREBRAL ŒDEMA.

Membranes of the Brain.—The dura mater and arachnoid are usually thin, and upraised by serum. The chief phenomena of morbid exaltation seem to take place in the pia mater; it is thickened, of a pale rose colour, varicose in appearance, and sometimes filled with granulations, or albuminous concretions; it is bathed in serum. This serum has no longer its usual colour and transparency; it seems darker, and sometimes filled with whitish flakes; it presents to the touch an acridness and fluidity that are peculiar, the serum in ordinary state being more viscid.

Brain.—The upper and lateral convolutions are flattened, and pressed to each other; the anfractuosities disappear, or seem only like mere lines; they are often found adherent in several places to the pia mater.

Grey Substance.—This is the first part that is affected in cerebral œdema. Being in constant contact with the serum, it loses its natural colour, swells, and becomes spongy; its consistence, notwithstanding, is but seldom diminished; there is a true infiltration, whether it be chemical or mechanical, of the inter-globular cellular tissue. Even the vessels of this substance no longer contain any blood; they are engorged with the same limpid serum that envelopes the brain. It is owing to this engorgement that we see the drops oozing out from the incisions of the cerebral substance. This imbibition of the external cerebral matter seems to us a very remarkable fact; it seems not to prevail to anything like the same extent on the white substance, although it is found there also; the drops are forced out by pressing it in the same way, but they are not so large. If, moreover, we tear the white substance, we see at the bottom of the laceration whitish filaments, which are the capillaries injected with serum, which, traversing from side to side, when torn, allow the serum to escape in drops. In the normal state, these capillaries contain red or black blood.

In one case alone of these nine, was a species of cerebro-spinal *anasarca* observed, which filled both the external and internal cavities of the encephalon. In all the others, the œdema was partial, and limited to the superior lateral region, or the anterior or posterior region of the brain. In none did we find the fluid descend to the base of the brain. In one patient only did the fluid penetrate into the ventricles, which are generally flattened and compressed. The almost constant arrangement by means of which the serous accumulation is circumscribed in the upper parts of the brain, proceeds, no doubt, from the weight of the brain itself on its basis, and also from the pressure which the accumulation of the serum in the upper part produces on the whole surface of the brain towards the base.

Cerebral œdema is not, as might be supposed, an isolated disease accidently developed in the insane; it depends on a lymphatic predisposition in individuals, and is complicated most commonly with œdema of other parts of the body, in the splanchnic cavities, in the limbs, the wrists, or ankles. This general affection is additional proof that it is chiefly through the cellular tissue that serous infiltrations are propagated whether in the brain, or in any other organs.

But by what mechanism does this serous exhalation take place? Is it by the obliteration of the veins which can no longer absorb, and the action of which is necessary to this function? Or are we to admit that in cases of the insane the irritation of the cerebral pulp, which produces the delirium, is transformed into a secreting irritation which causes the abolition of the intellect? In spite of the reserve which scientific severity imposes, we must not be timid in regard to some explanations, when they result from positive facts, and which for the rest, every one is at liberty to account for in his own way.

We can readily conceive in persons of lymphatic temperament that a brain already irritated which cannot think rightly, and whose faculties are exalted, the affection of the brain may re-act in its turn on the pia mater, rendering its exhalant functions more active, and finally extending to it its own morbid exaltation. The pia mater then becomes red, and thickened; its vessels dilate and secrete a quantity of serum more than natural, and the absorption being no longer equal to the secretion, an accumulation takes place between the membranes and the brain, in the same manner as in other serous cavities. A new cause of compression on the brain then arises, which changes maniacal state into one of apparent calm, and at the length by its rapid increase, paralyses the intellect, locomotion, and sensibility. We shall now take a glance at these symptoms, and their progress.

Symptoms of Œdema of the Brain.—They first shew themselves by lesions gradually affecting the *general sensibility*, subsequently involving *locomotion*, and lastly the *intellect*.

The Lesions of the Sensibility, ought to be examined at two different stages; at the time of the serous exhalation, and after its accumulation has become considerable. In the first stage, the skin in several of its regions becomes insensible; in some patients, the pulp of the fingers is the seat of singular sensations; some feel a peculiar numbness and cold, either in the limbs, or in certain parts of the back, or belly; others that they are not clothed, that they are naked, even the thickly clothed.

When the œdema of the brain is established, we have seen in some of the cases how complete the insensibility becomes, even in parts naturally the most irritable. Not only may the skin be pricked, or burned in certain places, without causing the slightest appearance of pain, but even the most sensitive mucous membranes—those covering the eye, nostrils, and mouth seem to be wholly insensible. I have seen one of these patients cured of an accidental stupor that had lasted three months, and during her malady the insensibility was so complete, that several seton-needles were passed into the skin of the abdomen without giving rise to the slightest pain; and what is still more remarkable, she looked on while this was being per-

formed with an air of satisfaction. In one case, snuff dropped on the conjunctiva produced no feeling of pain. In the other cases, ammonia and sulphuric æther were equally inoperative on the sense of smell or taste.

For the rest, this species of insensibility or paralysis seems to be entirely confined to the external senses; for although the globe of the eye is insensible, vision itself is perfect; the patients can see and distinguish objects and persons perfectly; they hear every thing that is said to them, but they cannot reply.

Lesions of mobility.—The most characteristic symptom of the attack of cerebral œdema is the sluggishness and numbness of the limbs. Moving seems an enormous effort to the patient. This numbness differs from paralysis, inasmuch as the movements, although difficult, are still possible, but only by a violent effort of the will. The patient will remain for hours in the erect posture without stirring in the least. Some of these cases exhibit examples of a peculiar lesion of mobility greatly resembling catalepsy; and it is by no means impossible that catalepsy, which consists of rigidity through excess of contractility, and of which the organic cause has scarcely been enquired into, may be in many cases simply the result of mechanical compression on the brain from serous effusion on its surface, or into the ventricles, and that, according to the extent and seat of such effusion on the anterior or posterior lobes, the cataleptic symptoms would be observed more particularly in the upper or lower extremities.

In cerebral œdema, the lesions of the intellect are much more marked than those of mobility and sensibility. The most petulant maniacal agitation, the most violent delirium, are suddenly followed by perfect calm and the appearance of reason. The patient has the most singular hallucinations; his memory and attention are the first of his faculties that become disordered; the ideas become confused, vague, and clouded; the utterance slow, difficult, and at last impossible. When the œdema is more advanced, there is no longer any perception, the whole understanding is suspended, but, singular to say, the patient retains a consciousness of his state. When recovery takes place, the patients state that they were aware of their position, but they had not the power, the will, or even the desire, of changing it. The moral sentiments are likewise completely altered; all the affections, and even the instinct of self-preservation, that persists so strongly, even in the imbecile, are completely overthrown.

Progress of the Disease.—Cerebral œdema begins by vague symptoms of headache, a sensation of tightness and pain around the skull. The memory and attention are the chief faculties that are disturbed. The organs of taste and smell and the skin are benumbed in the beginning, as has been observed by M. Demazy. At a later period, the cerebral functions are more deeply impaired, the mouth gapes, the countenance is stupid, and the eyes dull; the intellect is null, and the senses seem paralysed. The organic functions are now involved: the alimentary canal participates in the paralytic atony that seems to extend over the entire body: hunger, thirst, and the excretions seem as it were suspended; the movements of the heart become remarkably slow, the pulsations falling to forty, or even thirty in a minute.

We can easily conceive that a disease which seems, as it were, the asphyxia of the intellect, although serious in itself, may nevertheless be rarely fatal, and in fact we owe the opportunities we have had of studying its pathological effects on the dead body, to the other morbid complications with which it happened to be associated. M. Demazy had met with but five cases in examining the bodies of three hundred and twenty insane patients; and during a period of nine years, I myself met only the five cases narrated. Yet acute stupor is by no means uncommon in the insane; but it is cured almost always after the lapse of a few months.

The following gentlemen were admitted members of Apothecaries' Hall on the 19th June, 1845:—W. H. Colborne, H. W. Laver, Fred. F. Kingdom, E. C. Odling, Orlando Salathiel Winstanley.

LECTURES ON PHYSIOLOGICAL ANATOMY, THE SPECIAL PHYSIOLOGY OF MAN, AND ON THE ANATOMY OF TISSUES—MORBID AND HEALTHY.

By Dr. Knox, F.R.S.E., F.R.C.S.E.,

Corresponding Member of the French Academy of Medicine, and Lecturer on Anatomy and Physiology, &c. &c.

Bones of the Face (continued).

The lower jaw-bone may be divided into a dental and an articular portion; the descriptive anatomist speaks of it otherwise. Few bones have presented greater difficulties to the philosophic anatomist than the lower jaw-bone; in the mammals, composed of only two portions, even in the youngest fœtus; in the crocodile and other analogous animals it is composed of several separate bones; how is this? Does the doctrine of *unity* of organization then not extend to all the vertebrata? Or is it that the germs, though existing, are never apparent in man and the mammals? I lean to this latter opinion, believing the doctrine of the unity of the organization to be a correct one when properly stated; that is, correctly expressed. In man, at birth, this bone is composed of two portions, which afterwards unite by bony union at the symphysis; this union takes place soon after birth, and proceeds from below upwards. As we advance in years, the form of the bone changes so much, that the lower jaw of a very aged person and of an infant come at last to resemble each other. The alveoli disappear, and this causes the loss of the teeth. An intermediate bone has been said to have been sometimes found in the symphysis. The persistence of the cartilaginous union at the symphysis has never been observed in man.

Let us pass over the teeth at present, whose physiology will be more appropriately considered when considering the organs of digestion, and finish what I have to say in respect of the skeleton of the cranium and face.

Sutures or Joints.—All the bones I have spoken of are united to each other by joints, called sutures and harmoniæ; the lower jaw-bone alone has a moveable articulation, with the usual apparatus of such a joint.

1° Enumerate the sutures carefully, consider their various names; the old anatomists knew nothing of the principles of nomenclature. Observe, that however serrated externally, their edges are smoother internally, as if we should say, externally they are *sutures*, but internally *harmoniæ*. Sir Charles Bell and others of that school (the Socratic) assigned for this a *final cause*; but final causes are merely effects; they did not attend to this—this *method* was also objectionable on other grounds: his reasoning was *deductive* not *inductive*. The sutures disappear with age, which led the younger Soemmering to say, that in the cranium there was, properly speaking, but one bone.

2° The ossa Wormiana, or supernumerary bones, present great difficulties to the physiologist. They are found in most of the sutures and at the fontanelles; the pre-squamous bones, spoken of in a former lecture, may be considered as supernumerary bones, although some objections might be offered to this view. These bones (the supernumerary) are composed of both tables and a diploe: they often abound in the Scandinavian head, and are seen rarer in the crania of the dark races; in hydrocephalic heads they are often found extremely numerous, and of a large size.

3. The number of cervical vertebræ has never yet been determined; but whatever that may be, it is probable that their growth to a certain extent is independent of each other; hence one segment, if I may so, of the skull, with the corresponding cerebral mass it supports and protects, may grow and be fully developed, whilst the adjoining ones may grow but imperfectly. There is now before me the cranium of an adult who was fatuous from birth; yet this cranium is at first sight perfectly well formed in all its parts; and so it seems until narrowly looked at, when I thought I could discover a peculiarity which has not, I think, been already explained; it is this, and here is the cranium. Now the several measurements of this cranium are excellent, and its whole appearance indicative of its having belonged to some one of sound and even of good intellect; all the regions seem to be well developed; that is, all the phrenological regions, as they are called, and yet the person was fatuous. That no doubt may remain as to this singular law I venture now to bring forward, I offer you all the more important measurements compared with those of an ordinary French head, not selected, but taken at random, from a number of others.

Measurements of the cranium of a fatuous person, compared with that of an ordinary or normal cranium.

	French Skull.	Fatuous.
Circumference—a tape measurement	20 5-8ths.	20 4-8ths.
Height from one meat. audit. exter. to the other ..	12 4-8ths.	12 4-8ths.
Breadth of forehead	4 4-8ths.	4 4-8ths.
Sphenoid bone.		
1° Greatest breadth of the larger alæ	1 1-8th.	5-8ths.
2° Where narrowest........	6-8ths.	4-8ths.

The pterygoid processes are not larger than in a child, and the whole bone bears the marks of imperfect development.

From these measurements may be deduced the singular law (provided it meet support from other crania) that a segment of the cranium, or a cranial vertebra may be imperfectly developed; that in this case it was the sphenoidal vertebra; that certain parts of the brain having a relation to this vertebra, partook of its development; that the functions of these parts suffered thereby, disturbing all its functions, and fatuity was the result. I need not remind you that many additional observations would require to be made before these laws would receive the sanction of cautious generalisers.

The cranium varies exceedingly in thickness in different individuals, without our being able to assign any cause for this. It becomes thinner with years. The parrallelism of the two tables has been a matter much debated, as on its fixity within certain limits at least is based the doctrine of craniology, as established by Gall, and even in some measure the cranioscopy of Carus and others; the phrenological doctrines of Spurzheim have no proper basis in nature. Now, generally speaking, the tables of the skull are sufficiently parallel to indicate the bulk of the subjacent brain, excepting as will be shown hereafter, in the region of the frontal sinuses. This parallelism, however, is not nice nor delicate, nor perhaps is it necessary that it should be so for any cranioscopic purpose. I learn from a note subjoined to the text of the "Encyclopædie Anatomique" that as early as 1807 the celebrated Soemmering wrote a memoir on some of these interesting points; the note contains the substance of that memoir, and is as follows:—

"There can be no doubt that there exist on the surface of the human cranium twenty-seven points, remarkable in certain individuals for their rounded, oval, and oblong prominences, which Gall described from nature, and which may be found in every collection abounding in crania. But it is not so easy to determine in how far these prominences indicate surely certain propensities and habits.

1° I recognised in his collection of crania the heads of distinguished musicians, artists, &c. without hesitation, as those of Blumann, Alxinger, Frenlein, and Frank, who had all been personally known to me.

2° Gall never was wrong in a single instance in recognising the cranium or head of a distinguished mathematician, astronomer, musician, or artist.

3° Gall cited Acrell's case inexactly.

4° The twenty-seven external prominences mark a similar number of concavities within the cranium.

5° The twelve prominences pointed out by Gall on the crania of some mammals and birds, do not correspond with those on the human cranium.

6° The name of organs cannot, with propriety, be given to the cerebral convolutions."

SUPPLEMENTARY NOTES TO THE PHYSIOLOGICAL LECTURES ON THE SKELETON OF THE CRANIUM AND FACE.

NOTE I.—*On Measurements of the Cranium.*

THE following note was kindly furnished me by Dr. Alexander, member of the Academy of Glasgow, who met with it in Müller's Archives, and translated it for me; it confirms what I had always believed in respect of the race which Mr. Van der Hoeven calls "Sclavonian," but which, with deference to these distinguished scholars, I think ought to be called *Sarmatian*. History shews that the Sarmatians were first met with near the mouths of the Danube, and on the northern and western shores of the Black Sea; and there we find them still. As a *race* of men, they are becoming extremely formidable to the liberties of mankind:—

Upon the Skulls of the Sclavonic People by J. Van der Hoeven; communicated by letter to Professor Dr. A. Retzius, of Stockholm, and inserted in "Müller's Archiv." for 1844.

You have, in your treatise "upon the forms of the North Sea crania," sketched a general character in the formation of the skulls of this race of people from four Sclavonian skulls at your command. From a comparison of a greater number of materials, this character I have been enabled throughout to confirm. I have examined and measured seventeen skulls, two of which belonged to Poles, and the remainder to Russians from several places. Almost all of these were characterised by the round form. (Forma ovato-rotundata.) I will, perhaps, at some future period, in my enquiries into the natural history of man (the first part of which, upon the Negro, you have so kindly taken and critically examined), give a few delineations and deliver some more extended remarks. At present, I will content myself with simply indicating the medium measurements which I have determined. They deviate in some measure from your conclusions, but give, on the whole, a surprising confirmation of your remarks, and more especially a new proof that it is really no insane undertaking to make use of the skulls to characterise the races of mankind.

1. Circumference of the skull . . 0,509 (Max. 0,545 Min. 0,472)
2. Length of the cranial arch from the nasal bones to the posterior edge of the foramen magnum . . . . 0,363 (Max. 0,396 Min. 0,345)
3. Greatest length of the skull . 0,175 (Max. 0,194 Min. 0,161)
4. Height of the skull from the anterior edge of the foramen magnum to the perpendicularly opposite point of the suture of the parietal bones* 0,137 (Max. 0,152 Min. 0,122)
5. Greatest transverse diameter of the skull between the parietal bones . . . . 0,140 (Max. 0,152 Min. 0,127)
6. Breadth between the temporal bones above the meatus auditorius externus . . . . 0,138 (Max. 0,146 Min. 0,126)
7. *a.*—Length of the foramen magnum . . . . 0,035 (Max. 0,041 Min. 0,031)
7. *b.*—Breadth of the same . . 0,030 (Max. 0,033 Min. 0,025)
8. Breadth between the greatest convexity of the malar bones 0,131 (Max. 0,140 Min. 0,116)
9. Distance between the outer edges of the orbits . . . . 0,112 (Max. 0,124 Min. 0,109)
10. Height of the upper jaw from the root of the nasal bone to the alveolar edge . . 0,066 (Max. 0,076 Min. 0,059)
11. *a.*—Height of the orbits . . 0,033 (Max. 0,035 Min. 0,029)
11. *b.*—Breadth of the orbits . . 0,037 (Max. 0,040 Min. 0,035)
12. Height of the under jaw from the chin . . . . 0,032 (Max. 0,039 Min. 0,023)
13. Height of the ascending ramus of the lower jaw from its articular process to its angle . . . . 0,070 (Max. 0,079 Min. 0,063)
14. Distance from the chin to the angle of the lower jaw . . 0,083 (Max. 0,092 Min. 0,072)

* I follow here your definition. In my earlier researches I took the height from the posterior edge of the foramen magnum, which measurement gives a greater height.—[J. Van der Hoeven.]

NOTE II.—*On the Præsquamous Bones.*

I lately had an opportunity of observing in the cranium of a young Chimpanzee, that the *præsquamous bones*, as I have ventured to call the supernumerary bones completing that portion of the wall of the cranium between the great wing of the sphenoid, the parietal and the squamous plate of the temporal, formed in this young head a system or chain of bones, which in the *hydrocephalic human head* becomes amazingly increased in number. I shall return to this curious subject, when describing the development of the human skull from the earliest period, to birth, or full term. The reader will be pleased to observe, that in the preceding lectures, which are intended to be altogether practical, I have almost wholly devoted myself to the adult skull, and to its development at or near the full grown fœtus of nine months.

PROGRESS OF FRENCH SCIENCE.

FROM OUR OWN CORRESPONDENT.

Paris, June 7, 1845.

Academy of Sciences; Sitting of the 2nd June; M. E. de Beaumont in the chair.—Received: Report on the Extinct Mammalia of Australia, and on the Geographical Distribution of Pliocene and post Pliocene Mammalia in general, by Professor Owen, F.R.S., &c. Transactions of the Royal Irish Academy, vol. XX. Address on the Recent Progress of Geographical Researches in the United States, delivered at the Fifth Annual Meeting of the Association of American Geologists and Naturalists, held at the City of Washington, by H. J. A. Rogers, Professor of Geology at the University of Pennsylvania.

On the Density of Urine, and the Quantity of Salts Contained in it. By M. H. Chambert.—The author performed the following experiments: the urine was examined: 1° every hour for twenty-four hours; the result was:—

	Quantity of Urine Excreted.	Density.	Quantity of Salts contained in the Urine Excreted	Quantity of Salts in 1000 Parts
Maximum	1590	1·0347	23·636	18·055
Minimum	685	1·0176	6·993	8·161
Average	1034·375	1·0256	14·854	13·024

The author attributes the difference in density between his and M. Becquerel's experiments to the low temperature at which it was taken, and the greater quantity to the age and sex of the individuals and the means of collection which were employed; 2° Urine excreted immediately after taking food:

	Quantity.	Density.	Salts.	Salts in 1000 Parts.
Maximum	424	1·0379	10·658	21·370
Minimum	137	1·0210	2·126	11·190
Average	273·5	1·0271	4·640	16·394

3° Urine excreted the first thing in the morning:

	Quantity.	Density.	Salts.	Salts in 1000 Parts.
Maximum	686	1·0350	10·070	19·102
Minimum	274	1·0147	1.227	3·580
Average	447·96	1·0227	4·261	9·332

4° Urine excreted immediately after drinking:

	Quantity.	Density.	Salts.	Salts in 1000 Parts
Maximum	672	1·0121	14·208	21·137
Minimum	523	1·0070	1·288	2·463

From these facts it may be concluded: 1° That in urine excreted after taking food, the density is greater, and the salts in greater proportion than in that of the morning; 2° That the inorganic principles in the urine are in direct proportion to the quantity of salts introduced into the economy with the food; 3° That the salts are more abundant in the urine excreted in the morning, than in that after meals: 4° That there is no relation between the quantity of salts and the density; 5° That there is no exact relation between the density or the quantity of salts and the organic matter.

On the Action of Saliva on Fecula at the Normal Temperature of the Body, and on the State in which Starch is found in Cerealea after Mastication. By M. Lassaigne.—From the facts contained in the memoir the author concludes: 1° That starch or fecula, in the state of aggregation in which it exists in different substances, is not changed by the saliva at the temperature of the bodies of the mammiferæ: 2° That during mastication of the seed of amylaceous cerealea, starch is not disaggregated by the teeth, as some physiologists supposed, and consequently, that this principle cannot be changed into dextrine in the series of organic acts preceding the stomachic and intestinal digestions; 3° That in the horse on which the experiments were performed, the metamorphosis of starch into dextrine does not take place; not only because in the oats chewed and swallowed the globules of starch are entire, but likewise because, even if they were better chewed and crushed by the molar teeth, the saliva of this animal has not the action on their interior which is observed in human saliva; 4° That human saliva, which is without any action on uncooked starch at 100° F., acts on disaggregated starch even at 64° F. to 68° F., changing it partly into dextrine, and partly into glucose, the envelopes of the globules, however, still retaining the power of being coloured blue by iodine; 5° That in individuals who live on fecular substances, cooked or fermented, the starch contained in these substances must undergo the changes just mentioned, independently of the action which their saliva has upon the principles soluble in water.

Report on a Memoir of M. Blanchard relative to a Sea Parasite, by M. Milne Edwards.—This parasite is found under the mantle of an acephalous mollusc of the genus mya; it is very like that described eight years ago by Othon and Fred. Muller, and more recently by M. de Blainville, as a type of the class of Malacobdella; it differs from the common leech inasmuch as the ganglionic chain does not exist in the mesial line, but laterally, on each side of the œsophagus there is a ganglion which represents half of what constitutes the brain in the mammalia. These two ganglia are united by a narrow band, which passes over the digestive canal; the nervous chords which proceed from them, descend on each side without offering any other ganglia, except at their extremities, near the anus.

On a New Organic Compound.—The following extract is taken from a letter which M. Volher addressed to Professor Dumas:—"I am occupied in making researches on a very remarkable organic compound, which forms the bezoar of the East, and which is quite different from lithofellic acid. It is a crystallizable acid, insoluble in water, composition represented by the formula—$H^2O+C^{14}H^4O^7$: with potass, it forms a salt of a bluish-black colour: formula—$KO+C^{12}H^4O^7$. It speedily absorbs the oxygen of the air. It is especially in a physiological point of view, that bezoardic acid is interesting, for either it originates in the bile of the animals which furnish the bezoar, or it is an immediate product of their food.

On the Properties of Sulphur, by M. Daguin, Professor of Physique at the Royal College, Tours.—The conclusions of the author are: 1° that the transformation of soft into brittle sulphur may be accelerated by heat (4th experiment), and perhaps by the light of the sun (2nd experiment); 2° that it is hastened by mechanical action, and by a temperature of 212° F. (5th experiment); 3° that by keeping the sulphur at a fixed temperature, the transformation may be considerably retarded (6th and 7th experiments); 4° that when sulphur passes from the soft to the ordinary state, the transformation commences internally (1st experiment); 5° that when sulphur is cast at different degrees of heat, in that obtained at the point nearest the ebullition, the transformation takes place slowest. Thus soft sulphur, obtained by means of sulphur melted at 500° F. and cast, is

changed with greater rapidity than that which is cast at 752° F.

On the Laws which Govern the Saturation of Compound Bodies, by Ch. Gerhardt.—From the researches contained in this memoir, the author concludes:—1° that the unibasic acids (nitric, acetic, formic, benzoic, cinnamic, cuminic, butyric, valerianic, &c.) form only neutral ethers and neutral amides, and cannot furnish either vinic or *amidic* acid; 2° that the bibasic acids (sulphuric, carbonic, succinic, adipic, camphoric, &c.) form a neutral ether and a neutral *amide*, as well as vinic and *amidic* acids, these two last being unibasic; 3° that nitrogenised compounds have the same bases as the substances from which they are derived; 4° that *amidic* and vinic acids have never the same bases as the acids from which they are derived; 5° that the composition of the neutral *amides* and others may be of use in discovering the bases of the corresponding acids; 6° that the bases of compound bodies obtained from sulphuric acid and organic matter, may be a means of ascertaining the equivalent of the latter.

On Artificial Anatomy.—Dr. Sardaillon presented several anatomical preparations destined to facilitate the study of midwifery, the change of position and form of the different organs during gestation being shown.

Academy of Medicine; *Sitting of the 3rd June*.—M. Caventou in the chair.

On Inoculation in Syphilis.—Dr. Lagneau read a report on a memoir of Dr. de Castelnau relative to inoculation as a means of diagnosis in syphilitic affections. The learned reporter shares the ideas of the author in considering inoculation to be dangerous, and not so useful as has been supposed in the diagnosis of syphilis. Conclusions: thanks to the author; insertion in the bulletin of the Academy.—Dr. Londe: Though a member of the commission, still I have several objections to make to the report.—Dr. Dubois, of Amiens, enquired if Dr. Londe had read and signed the report.—Dr. Londe stated "that he had done neither one nor the other, but he did not consider that a reason why he should not be heard.—Prof. Moreau considered such a mode of proceeding would be very irregular; when a committee was named, the members ought to meet and discuss the various questions, so as to come to a general conclusion.—Professor Gerdy: If it were requisite ere a report could be made, that the members forming the committee should meet and discuss each article separately, none would ever be presented. It is well known that the report is generally the work of the reporter alone, and therefore we must not be too strict, or we run the risk of never hearing a report.—Dr. Dubois, of Amiens: Were the ideas of Professor Gerdy adopted, it would be more simple to name one member alone. But if there are questions in which the Academy may swerve somewhat from the regulations, there are others in which the opinion of a single member is not a sufficient guarantee, and such is the one now under consideration. Dr. Lagneau attacks a doctrine, a method of diagnosis, and yet neither of the other two members of the committee (Drs. Londe and Martin Solon) have read the report; in this state of things, I propose sending the report back to the same commission.—Professor Adelon, after seconding the proposition, stated that he had formed part of three committees, and that a report never was presented without the members being united and being made acquainted with the report.—Dr. Renauldin requested that another member might be named instead of Dr. Martin Solon, who was very unwell.—Dr. Londe: If I cannot give my opinion because I am a member of the commission, I here offer my resignation.—After some further remarks from Professors Moreau, Gerdy, and Cloquet, the report was sent back to the same commission.

On Pellagra.—Dr. Jolly read a report on this disease in reply to a letter from the Minister of Public Instruction, relative to the important opportunity for the publication of the documents on this disease forwarded by the *Conseil Central de Salubrité* of the Gironde. The learned reporter after examining the documents sent to the committee relative to the cases of pellagra, observed at St. Louis, first by Dr. Th. Roussel, and afterwards by Dr. Devergie, and bringing forward the opinions of the different writers on the nature, causes, and treatment of this affection, gives a general description of the diseaseand terminates by proposing to reply:—1° That the documents forwarded by the Conseil of the Gironde, on which the opinion of the Academy is solicited, establish beyond a doubt that an endemic disease exists in the *Landes*, which presents all the characteristic symptoms of the pellagra of Lombardy. 2° That these documents and the two drawings which are added to them are highly valuable to science, and very important to the government, inasmuch as they reveal the existence, give an exact description and present a faithful picture of a disease hitherto but little, if at all, known in France. 3° That in adding to these documents the facts which shew the existence of pellagra in the neighbourhood of Paris, and in some parts of the South of France, they become still more interesting, since they shew the danger of the propagation of this affection in other localities than those in which the practitioners of the Gironde first observed it. 4° That consequently the Academy considers it advisable to publish these documents speedily and extensively. 5° That as to the cases communicated by Drs. Gibert and Devergie, physicians to the Hospital St. Louis, though it was impossible to comprise them in the preceding conclusions, still they are worthy of the attention of the Academy, and of the profession, and consequently the committee have the honour of proposing,—(*a*) That these cases be sent to the *Comité de Publication*; (*b*.) that their authors be thanked for their interesting communication; and (*c*.) that they be requested to inform the Academy should any new cases of pellagra be observed in their wards.—Dr. Rochoux. Though I am of opinion that the conclusions ought to be adopted, still I think it useful to offer a few remarks on the analogy which the reporter states to exist between pellagra and lepra, the more so, as I consider these two affections essentially different. The pathognomonic signs of pellagra consist in small maculæ surrounded by an areola, not above the skin, and so insensible, that the part may be pricked without the patient's knowledge; as the affection proceeds, this insensibility increases with or without tumefaction, and finally a toe, a finger, or even a limb may be detached spontaneously, and what is remarkable, without causing the slightest hæmorrhage. As to the action of the rays of the sun, I cannot admit this cause, except when the skin was previously affected; otherwise what would become of the poor Africans? Finally, lepra is, and pellagra is not, hereditary.—Dr. Husson enquired if any drawings had been sent, and on receiving a reply in the affirmative, requested that a wish for them be expressed in the conclusions.—Dr. Rousquet. Dr. Briere de Boismont informs me that he has three drawings representing this disease, and that he will have the honor of offering them to the Academy on the next sitting. Dr. Gaultier de Claubry had opportunities of studying pellagra in the Valais, in the *Landes* in 1809, and in the Asturias, and he constantly observed it in poor and wretched individuals.—Dr. Jolly. The remark just made is interesting, inasmuch as it proves, that pellagra existed in the Landes previously to the epoch mentioned (1818) in the documents. As to the observations made by Dr. Rochoux, the two diseases mentioned were not considered to be analogous, and inoculation was classed among the secondary causes. Dr. Prus regretted that no mode of proceeding was indicated by which the propagation of the disease could be prevented. Dr. Jolly in reply stated that the Academy had been requested to say whether the publication of the documents forwarded would be of any practical utility, and nothing more. The conclusions were then unanimously adopted.

Paris, June 12th.

On *Diseases of the Eye*, by Professor Velpeau.—*Iritis—Treatment* (continued).—Besides the remedies mentioned in the preceding lecture, many others have been recommended as specific, but it will be presently shown how far this opinion is correct. These remedies are:—*oleum terebinthinæ*, in doses of ℥j. ʒx., and even ʒxiv. per diem; really, this a horrible remedy, against which the stomach rises, and which causes in almost every case, vomiting, diarrhœa, colic; in short, a violent and dangerous derangement of the system. It may, it is true, succeed, on account of the severe revulsion it produces; but, truly, I do not know whether it is not better to be affected with iritis, than to be submitted to a remedy which causes so violent a shock, and, indeed, I would never recommend it. *Purgatives frequently repeated*.—I have prescribed them, but must confess that the revulsion they produce does not appear to effect sufficient improvement for me to consider them of any great advantage. The amelioration is by far too slow, besides which, from the length of time it becomes necessary to administer them, they may be productive of serious mischief; they ought, therefore, to be given only when no other remedies can be had recourse to. *Astringents*.—Several have been recommended, such as catechu, kino, simarouba; but, in reality, they possess no efficacy. It may, therefore, be affirmed, that with the exception of venesection and calomel, as yet no remedy has any very efficacious action, and as the only disadvantage attendant upon the latter is salivation, which may, however easily be kept within proper bounds, I consider it ought always to be preferred until something better be indicated. *Specific Iritis*.—Although I have already stated the reasons why I do not, with the exception of the syphilitic, admit the existence of the specific forms of iritis, yet they must not be passed over in silence; first, because much has been said concerning them, and secondly, to avoid the injurious results which necessarily must happen if this affection is combatted by remedies destined to attack the supposed principle of the disease. It has been considered in two different ways, for the French practitioners do not view it in the same light as the modern German authors: in the opinion of the latter when an individual offers the signs which they think indicates a syphilitic origin, the disorder is specific; again, if another presents the characters assigned to rheumatic or scrofulous iritis, the affection is specific, even if the patient had never suffered from syphilis, rheumatism, or scrofula. From what I stated in commencing the description of iritis, it is not necessary for me to take up much time in combatting this mode of appreciating the disease. As I then observed, though I admit that disorders are modified more or less by the constitution, *still I do not* think this sufficient to constitute a specific affection. In fact, iritis never presents in a strong and robust individual the same symptoms as in a weak and debilitated person, but this takes place not only in diseases of the eye, but also in all the maladies with which the economy may be affected: the same remarks are applicable to scrofula, rheumatism, &c. Those who have adopted opinions in opposition to those just announced, assign to each variety—which they call specific pathognomonic characters. Thus, they recognise *rheumatic iritis*—by intense photophobia and lachrymation; a distinct circle around the cornea; pain more or less violent, in the morning more than in the evening; pupil ovoid from above downwards. *Syphilitic iritis*—by a peculiar yellowish, copper tint of the iris; redness disseminated over its surface; nocturnal pains; pupil deformed so as to present a point upwards and inwards. *Scrofulous iritis*—by considerable spasm of the lids; photophobia and epiphora; pupil ovoid, offering a point upwards and outwards. *Arthritic iritis*—by the brilliancy of the eye; the iris appearing as if moist, and covered with a sort of froth; pupil offering an ovoid horizontally; finally, there are symptoms by which they distinguish typhoid, nervous, scorbutic, and numerous other species: for when once this method is adopted, there is no reason why we should not recognise a pleuritic, pneumonic, or peritonitic iritis.

If these doctrines had been established by men eminent in medicine, they ought to have proved that rheumatism depended on a peculiar virus, before they asserted that iritis was modified by this virus Now this has never been done; indeed, at the present time, many distinguishe practitioners con-

sider rheumatism to be only an inflammation of certain tissues. Again, there are only a few who admit that scrophula is owing to a peculiar specific virus, independent of the constitution of the individual. If, therefore, the generality of practitioners deny that a peculiar virus exists in each of these diseases, how is it possible to affirm that a specific iritis may be produced through the influence of this virus? This leads us naturally to the doctrines professed in France, viz:—that iritis may be modified by the constitution, or by diseases, which complicate or precede it, but without presenting any specific character, for were this admitted in iritis, it must be also allowed in other affections, since all are more or less modified by the constitution. Moreover, as I have already stated, the characters assigned by German writers to arthritic iritis, are frequently to be seen in my wards, where I have not, for the last fifteen years, observed more than two or three individuals affected with gout. The same remark is applicable to rheumatic iritis, as I have frequently remarked it in persons who have never suffered from rheumatism.

But it is not so with syphilitic iritis; on the contrary, whenever we observe the symptoms of this variety, we may affirm that, in one-half the cases, the venereal taint is present; but as a great many patients, from shame or other causes, deny strenuously ever having been affected with lues, too much faith must not be placed in their statements. Whenever, therefore, the patient owns to having suffered from syphilis, or if, notwithstanding his denial, there is any reason to suspect that such is the case, I admit that the affection is specific, because it is certain that the disease originates in a peculiar virus introduced into the system. But though I consider syphilitic iritis to be of a peculiar nature, must it necessarily be supposed that I think the characters assigned to it are pathognomonic? By no means; on the contrary, I have seen most of its symptoms in acute iritis, whilst they were completely absent in the syphilitic form. Thus, the shape of the pupil is by no means an infallible sign: and, on reflection, it seems singular to think that syphilis could give to the inflammation of the iris so peculiar a mode of development, that the pupil should present one form in preference to all others. I do not hesitate to affirm, from clinical observation, that the pupil may present, in the same stage of iritis, five, six, or even ten different shapes; nay, more, that it is not impossible to see the pupil take several different shapes in the same attack of iritis, and in the same person. The symptoms relative to the colour of the iris are not so fallacious as the preceding. It is well known that in constitutional syphilis, the skin presents a peculiar copper colour: now I have repeatedly sought for it in simple acute iritis, but could never find it; a peculiarity must here be mentioned, viz., that in individuals whose iris is naturally of a brownish colour, this part may assume a coppery tint, which, if not known, may become a source of error. It must also be mentioned that, in chronic cases, this tint is more highly developed. It may, therefore, be concluded that in syphilitic iritis, the part presents a peculiar colour. As to the other symptoms assigned as pathognomonic of the various species of iritis, yclept specific, a brief enumeration will suffice, as in reality, they are in nowise characteristic. For instance, the intense photophobia and epiphora of rheumatic iritis, exist only when there is a complication of keratitis or slight retinitis—diseases very frequent after rheumatism—the spasm of the orbicularis, the epiphora, and the photophobia of scrophulous iritis, are likewise symptoms of ulceration of the cornea, because it is only in those cases that they are met with. I do not, therefore, think it necessary, except in syphilitic iritis, to employ any particular remedies; the more so, as those recommended are far from being real specifics. How far this opinion is correct, will be examined in the next lecture, after which I will commence the description of chronic iritis.

On Fissures of the Anus.—According to professor Blandin, the first symptom which leads the surgeon to suspect that such a disease exists is, violent pain during defecation, increasing after the act is ended, and lasting sometimes for several hours, constipation; extreme difficulty in introducing the finger, and when once this is attained it is forcibly compressed, owing to the contraction of the sphincter; this was erroneously said not to be observed in fissures of a syphilitic origin, for it is not owing to the cause, but to the seat of the disease, since whenever it is placed on a level with the sphincter, it is invariably accompanied by tension of the muscle; as to the opinion of Boyer relative to its being the cause of the fissure, professor Blandin considers it rather the effect, for it comes on almost always from the continual irritation produced by the fissure and the inflammation caused by the passage of fecal matter on the part. But if the constriction is consecutive, would it not be sufficient to heal the fissure in order to obtain a cure? I do not think so, for the stools will always produce a relapse; an operation consequently is indispensable, and the subcutaneous method ought to be preferred to that proposed by Boyer, inasmuch as the wound heals sooner, and is not so frequently followed by bad consequences, phlebitis for instance. As to the incision, it ought to be made laterally, because by cutting forwards, the bladder may be wounded; and backwards, it must be very deep in order to divide all the fibres of the muscle. The division performed, the lips of the wound must be kept separate by tents, smeared if necessary, with soothing ointments.—*Gazette des Hopitaux.*

Incontinence of Urine.—Several cases of this affection have lately occurred in the wards of Dr. Robert, at the Hospital Beaujon. The usual remedies (strychnine, opium, &c.,) having failed, the urine was carefully examined and found to deposit a considerable quantity of a thick ropy mucus, which, added to the increased sensibility of the organ when catheterism was employed, evidently indicated the existence of cystitis; consequently the following remedies were had recourse to. Injections of decoction of marsh-mallow root, and poppy heads, semi-cupia, leeches, cooling drinks, and balsamum copaibæ. In one case the cure was complete, and in the three others there was an evident improvement.—*Annales de Therapeutique.*

Tubercles of the Testicle, the vas deferens, the Prostate Gland and the Brain.—M. Mouchol, *interne* to the Hospital *du Midi*, publishes the following case. Carré (Chs,) painter, ætat 19, after leaving the wards of Dr. Lugol at St. Louis, entered those of Dr. Vidal de Cassis, on the 8th Jan. 1845.—*Testicles*, right, quite sound; left four times as large as the other, softened; *vas deferens*, on the left side, had undergone the tubercular degeneration, was voluminous, hard, and uneven; he had cicatrices under the jaw, near which were several enlarged glands. An incision was made on the testicle, allowing an unhealthy looking, flaky fetid pus to escape; the opening was allowed to remain patent, the ioduret of potassium was given internally. This treatment was continued without anything occurring until the 15th March, when the patient complained of cephalalgia; the ioduret was suspended until that symptom disappeared, and was then recommenced—26th, the cephalalgia re-appeared, and the ioduret was stopped.—3rd April. The patient muttered incoherently, pulse regular, and natural; Dr. Vidal de Cassis diagnosticated tubercles in the brain, and prescribed leeches behind the ears.—5th, stupor; stupid look; can still understand when spoken to, but replies slowly and in monosyllables; tongue moist; stools natural; pulse as before. Blister to the nape of the neck. During the day, delirium, and jactitation, the straight-jacket became necessary.—6th, increased stupor; abolition of the intellectual faculties; face red; eyes motionless, staring; pupils dilated; conjunctiva injected and purulent; lips dry; continual motion of the arms; breathing, sighing, and frequent, pulse as before. Ice to the head, blisters to the thighs; death on the 7th. *Autopsy Brain*, presented several tubercles of the size of a nut; one was situated at the posterior part of the fissura magna sylvii on the right side, at about a line from the surface, so that it could easily be felt on pressure; a second was likewise found near the surface of the central lobe of the left side; a third somewhat further back than the preceding; three others of the same size were discovered on the inferior surface of the tentorium cerebelli on the right side, to which they adhered; the cerebral substance was injected throughout its whole extent; same state of the pia mater around the tubercles; no softening nor change of colour of the cerebral mass.—*Lungs*; full of granular, miliary, transparent tubercles.—*Testicles*; left completely destroyed, its fibrous envelope alone remaining, and tubercular matter occupying the place of the gland: epididymis united to the testicle; vas deferens having undergone the tubercular degeneration, has considerably increased in size, as high as the inguinal canal, after which it assumes its natural dimensions, increasing again as soon as it has reached the abdominal cavity, where it presents numerous tubercles; vesicula seminalis on this side larger than the opposite, and converted into a tubercular cavern which communicates with another in the prostate gland; this last finally opens into the urethra on the left side of the verumontanum; this opening does not appear to have been produced by a rent, and allows the point of a probe to enter.—*Annales de la Chirurgie.*

Academy of Sciences, Sitting of June 9th, M. E. de Beaumont in the chair.—Received Observations made at the Magnetical and Meteorological Observatory at Toronto in Canada, printed by order of her Majesty's government, under the superintendence of Lieut.-Colonel Edward Sabine, of the Royal Artillery, vol. i., 1840, 1841, and 1842. Transactions of the Royal Irish Academy, vol. i.

Academy of Medicine, Sitting of the 10th June. M. Caventou in the chair.

On Pellagra.—Dr. Theophile Roussel addressed a letter in which after stating that he considered it incumbent on him on account of the vote which closed the last sitting, to communicate his researches on this subject to the Academy, he continued thus:—"Three years ago, on my return from travelling in Italy, I had an opportunity of observing and describing the first case of pellagra observed in Paris; this fact was published in the *Revue Medicale*, July 1842, a twelvemonth before those of Drs. Gibert and Devergie; I regret very much that the learned reporter was not aware of it. Since that I have perseveringly pursued my researches on this disease, and as I think I have obtained several important results relative to the causes, the origin, and the real seat of the affection, many of which are quite new, I have the honour of offering a copy of my Thesis, in which the most important are mentioned; I add a copy of the case published in 1842, and shall shortly have the honour of presenting my work on pellagra. In the meanwhile, in order to fix attention on the unfortunate populations afflicted with this disease, I consider it my duty to state that numerous attestations, and innumerable facts prove that the victims of this cruel affection increase daily, not only in the department of the Landes and of the Gironde, but likewise in all those near the Pyrenees, and especially in those of the Aude and the Haute Garonne. The documents communicated by Dr. Roussel, surgeon to the hospital of Castelnaudary, those published by Dr. Miguel, and, finally, those communicated to me by Dr Calis, a distinguished practitioner of Villefranche, shew the danger attendant on this scourge, but which may, by the joint aid of medicine and the public authorities, be put a stop to. On a future occasion I shall have the honour of communicating to the academy my researches on this subject. Dr. Briere de Boismont addressed a letter on the same disease, with drawings, representing the different phases of the characteristic eruption of pellagra, and a portion of the cuticle of a person affected with it. Dr. Ferrus: As I was not present at the previous sitting, I may be excused in asking, whether a complication was noticed in the report, I mean mania, or melancholia. I have had an opportunity of seeing many persons affected with pellagra at Milan, and in a great number it was complicated with mania or melancholia. The physician of the hospital in that city stated that this circumstance was frequently observed, and that though the affection was considered to be hereditary, still, by a proper treatment, it could be cured. I therefore perfectly coincide with Dr. Briere de Boismont in this respect; as to what he states with relation to pathological anatomy, I can

say nothing from personal experience, my stay at Milan having been too short for me to assist at any autopsies, but I was informed by competent judges that it is as Dr. Briere de Boismont has stated. M. Duprey presented some remarks on pellagra, which he compared to the diseased produced by secale cornutum.

Cow Pox.—M. Huzard writes, stating that having been informed that several cows near Senonches offered pustules of cow-pox, he went to the spot in order to verify the fact; unfortunately, the pustules were already dry, but a milk-maid, strong and hale, who had never been vaccinated, presented some characteristic pustules on the hands and arms, in the first stage. The matter collected was forwarded to the *Comité de Vaccine* to be experimented with. The farmer's wife and children, having been vaccinated, experienced nothing. Dr. Bousquet stated, that he had vaccinated several children, and that the result should be made known to the Academy.

Living Animalculæ in the Urine.—Drs. Kergaradec and Balestrier sent the details of this case and the animalculæ.

Inoculation of Syphilis.—Dr. Lagneau presented some remarks on the report presented at a former sitting, and proposed, that it be discussed, and the conclusions put to the vote. Dr. Londe considered that this ought to be delayed until Dr. Martin Solon could be present. Dr. Rochoux remarked, that it is necessary for a report to be signed by three members ere it could be discussed; now, in the present instance, two only had done so, but if agreeable to the Academy, he would affix his signature; in which case, the discussion could proceed immediately. The proposition of Dr. Lagneau, not having been seconded, was not put to the vote.

Gelatinous Capsules.—M. Lecanu presented a report relative to gelatinous capsules, for which the inventor wished to take out a patent. The reporter concluded, that there was nothing new, and that consequently, the patent ought not to be granted.

Nomination of Foreign Associates.—The Academy having decided, that a list of candidates should be presented, Dr. Paisect read a report, in which their titles were mentioned. According to the rules of the Academy, three candidates must be presented for each place; the number was, therefore, twenty-one, seven places being vacant, divided into three series,—in the first, the following gentlemen were named:—MM. Muller, Brodie, Burdach, Buffalini, Clark, Lawrence, Marshall Hall. M. Lusse proposed adding Liebig's name, and Professors Roux, and Velpeau, Havren, Salomon, Chelius, &c., Drs. Gerardin and Delens, on the contrary, considered that the list presented by the Committee ought to be maintained. Finally, after a long and rather tumultuous discussion, a decision was postponed until the next sitting.

Caries of the Inferior Maxillary Bone.—Professor Blandin gave the details of the following case:—A woman, about 25 years old, entered the wards of Professor Blandin, at the Hotel Dieu, for caries of the inferior maxillary bone. An operation being indispensable, it was performed as follows:—a semi-circular incision was made in the integuments under the chin, from the angle of the jaw, on the right side, to the left zygomatic arch, and by a careful dissection, the diseased portion was laid bare, and removed; for some time, the cheek on this side was sunken, but a ligament was afterwards formed, so as to replace the lost bone, in every respect; this felt like the lower jaw of an infant on coming into the world; the cheek, after the development of this tissue, assumed its natural form; the only consecutive accidents were several small abscesses.

GARLAND DE BEAUMONT, D.M.P., B.L., & S., &c.
Honorary Physician to the Spanish Embassy.

PROGRESS OF GERMAN MEDICAL SCIENCE.

By SIGISMUND SUTRO, M. D.

Diagnosis and Treatment of the Diseases of the Pancreas.—The symptoms of diseased pancreas, are: 1, painful sensation in its anatomical situation, the pains being especially severe towards the right hypochondrium, so that they may be readily confounded with disease of the liver; 2, swelling of the pancreas, presenting a rather hard tumor extending towards the left above the navel; 3, vomiting, not only after meals, but at other times, and often without any reference to the fulness or emptiness of the stomach. The vomited matter is a clear albuminous fluid, either insipid or of a saline taste. Such vomiting is only observed in inflammatory affections of the pancreas; if the liver is affected at the same time, the vomited matter appears greenish-yellow and has a bitter taste; 4. obstinate obstruction alternating with diarrhœa. Treble and quadruple doses of purgative medicines only produce a few stools, without difficulty in some cases, but in others, with colic and tenesmus; 5. impossibility of lying on either side (Jos. Frank says, de inflammatione pancreatis: Ægrotor. decumbendi modus varius, and page 367, de carcinomate pancreatis, alias impossibilis est situs in dorso, aut soli dorso incumbere cogitur æger.); 6. consensual pains felt simultaneously in the loins, shoulders, and back, not changing their seat like rheumatic pains, but remaining permanent for weeks; 7. dryness of the mouth and throat, or abundant salivary secretion. The dryness extends to the stomach, and cannot be alleviated by any remedy; 8. emaciation, often extreme; 9. the fever is slight but returns in consequence of the least excess; 10. hypochondryacis.—(*Dr. Melion in Oesterr. mediec. Wochenschrift.*)

On Antimonate of Potash.—It is not easy to prepare the antimonate of potash, so as to use it as a certain test of soda. Fremy distinguishes, 1. an insoluble antimonate of potash, (called the binantimonate of potash by Berzelius, the antimonium diaphoreticum ablutum of the ancients;) 2. a gummy deposit, (simple antimonate of potash;) 3. a deliquescent, and 4. a granular antimonate of potash; the latter only can be used as a test for soda. To obtain it, melt antimony with nitrate of potash, wash the mass with lukewarm water, dry the insoluble residue, and heat it with three parts of hydrate of potash, till the mass becomes soluble in water. If this antimonate of potash is then dissolved in water, two salts are obtained by evaporation, *a*, the deliquescent salt, to be washed out with cold water, till the residue has become granular, and *b*, the granular salt, which is white, and difficult of solution in cold water. Fremy considers it as isomeric with the gummy antimonate of potash, the solution of which gives a gelatinous precipitate with salts of soda, whilst the precipitate caused by the granular salt is immediately deposited in crystals. The granular antimonate of potash consists of

61,3 (1 atom) antimonic acid,
16,9 potash (1 atom,)
21,8 water (7 atoms.)

100,0

Its watery solution is not precipitated by a diluted solution of sal-ammoniac, whilst a precipitate is formed in the gummy salt. The cause of this difference lies in the circumstance, that the granular salt is bi-basic, for at 200°, it only loses six atoms of water and retains the seventh. At 300° it becomes anhydrous, like the gummy salt. The granular antimonate of potash will discover 1-300dth part of soda in solution. If the soda should not be immediately thrown down, the addition of alcohol will aid its precipitation, but then the precipitate must be washed with water. The test prepared as a watery solution will keep for some time, but ultimately it passes into the gummy, or even into the insoluble antimonate of potash, when of course it becomes useless. If the soda be combined with an organic acid, it is advantageous to transform it, before its precipitation, into a carbonate, muriate, or sulphate, because a flocculent precipitate is easily formed in organic salts. The anti-monate of soda possesses the same stœchiometrical constitution as the neutral (granular) salt of potash; for Fremy found it to be composed of

64,2 antimonic acid, (1 atom)
11,9 soda, (1 atom)
23,9 water, (7 atoms)

100,0

It also loses six atoms of water at a temperature of 200°. Several chemists maintain the antimonous acid of Berzelius is nothing but antimonate of oxide of antimony, $Sb_2 O_3 + Sb_2 O^5$. For if the so-called antimonous acid be treated with concentrated potash lye, antimonate of potash is obtained, and the oxide of antimony is separated by dilution with water. If the antimonous acid be melted with potash, the effect is the same; only in long-continued melting under the influence of the air, the oxide of antimony enters into a higher degree of oxidation, and only antimonate of potash is obtained. Those acids which combine with oxide of antimony, separate antimonic from the antimonous acid.—(*Buchner's Repertorium.*)

Hæmoptysis after the Use of Succus Citri.—Lemon-juice having been much recommended lately in dropsy, the author, in two cases out of three in which he employed the remedy, found its use followed by hæmoptysis. We transcribe his first case:—A strong, muscular joiner, with a high and broad chest, stood for a great length of time in water whilst at work on a mill in the summer of 1840, and in consequence he suffered from rheumatic fever, which was followed by ascites and anasarca. After the principal remedies in general use had been administered in vain, the patient took a tablespoonful of lemon-juice every two hours for several weeks, when he was suddenly attacked by such severe hæmoptysis that death ensued on the second day. The patient had never suffered from any complaint of the chest before. The author asks, did the exhibition of so much acid produce hæmoptysis, or was the fatal issue to be ascribed to other causes? (Though acids are generally used as styptics, citric acid does not act as such, but on the contrary, according to experiments on animals, it dilutes the blood.)—(*Dr. Klusemann in Preuss. Verein. Zeit.*)

PROGRESS OF ENGLISH, ITALIAN, AND AMERICAN MEDICAL SCIENCE.

THE SYSTEM OF NON-RESTRAINT.—A writer in the *British and Foreign Medical Review*, speaking of the non-restraint plan of treatment of lunatics, says: six years ago the experiment of non-restraint in all cases was tried at Lincoln, and a year subsequently Dr. Conolly, in the face of opposition, contempt, and scepticism, decided on making the bold experiment of abolishing mechanical restraint at once from Hanwell, where there were more than eight hundred and fifty pauper lunatics under his care. The experiment has been eminently successful. It has been followed by Lancaster, Gloucester, Northampton, and Haslar, where non-restraint and kindness have been carried to their fullest extent, and with entire success. The direct result has been the increased comfort and tranquillity of a large body of the lunatics by the diminution of much unnecessary cruelty and harshness to which they were before subjected, and the indirect result is that the law of kindness instead of severity is recognised in a greater extent than formerly in all lunatic asylums (with but few exceptions) and the condition of their unhappy inmates thereby improved. It has not prevented suicides; but from the statistics of Bethlem it is fair to conclude that it has diminished their frequency. It has not prevented accidents from sudden outbreaks of fury, any more than the restraint system; but there is no reason to believe that such have been more numerous. They belong to the nature of the disease, and no one plan, but the barbarous one of a complete and entire confinement of all who are not idiots or demented, would prevent them. The system which the Commissioners of Lunacy advocate does not, for these accidents have occurred chiefly in asylums conducted on their own principle, and have happened also where much more rigorous mechanical restraints have been the rule. But that the non-restraint system is of equal security with the other, both being somewhat insecure, is proved by the evidence of their report. When therefore the notorious abuses of the system of restraint, to which it is so peculiarly liable, are taken into consideration, and the great fact that by carrying out this new system to an extreme, so much good has been effected withou

any increase of the inconveniences experienced under the old system; we regret that the Commissioners have not given the more decided sanction of their authority and recommendation to non-restraint, and have not even fully recognized the advantages which it has already conferred, and those to which it must lead.

Analysis of the Urine of Insane Patients in St. Luke's Hospital in 1844.—Dr. A. J. Sutherland and Dr. Rigby have published, in a recent number of the *Medical Gazette*, a very important paper under this title, of which the following is an abstract:—The authors premise the rules which render patients inadmissible into St. Luke's Hospital. They are as follows:—1. The possession of sufficient means for decent support in a private asylum; 2. Having been insane for more than twelve calendar months; 3. Having been discharged uncured from any other hospital for the reception of lunatics; 4. Being troubled with epileptic fits, paralysis, or a state of idiocy; 5. Females with child; 6. Requiring (from disease or debility) the separate attendance of a nurse, or the assistance of a crutch; 7. Being under the age of 12, or above 70; 8. Being brought not clean, not properly clothed, and not free from infectious disease. Many patients are attempted to be passed off upon the hospital, who are known to be paralytic, and to have had epilepsy; but in all probability the majority of cases of paralysis, which are brought for admission, are not known to be such, either by the friends, or the medical men who send them. The paralysis of the insane is a disease very different from common paralysis; there is no disintegration of the nervous fibre in these cases, but an exhaustion, more or less complete, of the nervous energy, producing a state of general debility, and trembling of the limbs; the motor nerves do not refuse to perform their office, but they do it badly; hence the tremor of the upper lip and hands, the stuttering speech, the faltering gait. It is to be wished, that some other name than paralysis had been found to express this affection, because it leads to much error and confusion of ideas. It cannot be too often repeated, that general paralysis, or paralytic insanity, is an affection perfectly distinct from hemiplegia and paraplegia. The disease can at once be recognised by the peculiarity of the speech; the motor nerve of the tongue is generally the first to suffer; the exquisite play of the muscles becomes embarrassed, and produces hesitation and thickness of speech; the pupils of the eyes are sluggish, and there is usually asynchronous action present. The cases are arranged under the six following forms of insanity:—mania, melancholia, dementia, acute dementia, monomania, and puerperal madness; of these, the three first species, being by far the most common, have afforded the chief materials for investigation. The number of cases which were examined are as follows:—mania 56, melancholia 40, dementia 96, acute dementia 3, monomania 5, puerperal cases 9. The urine passed in the morning was selected for examination, as being least subject to the influence of food, and its investigation was arranged under the following heads:—color, acid, or alcaline, sediments, specific gravity, serous, excess of urea, lithic acid, lithate of ammonia, triple phosphate, oxalate of lime, carbonates, muriate of ammonia, muco-pus. Each of these has been made the subject of distinct investigation, and the relative proportion and per centage in which they occur, have been given in as many tables, from which the authors deduce the following summary:—That in mania and melancholia the prevailing colour of the urine is high: in dementia it is light. It is acid in at least 80 per cent., of the mania and melancholia cases; in dementia, the proportion is much smaller, viz. 63·54 per cent. Sediments of one sort or another occur in almost every case of mania and melancholia, especially the latter; in dementia, in only every other case. The specific gravity in the two former species ranges most usually between 10·21 and 10·30; that of melancholia frequently exceeds even 10·30, whereas that of dementia is usually found between 10·11 and 10·20. Serous urine was a rare occurrence, viz. 7·50 in melancholia; in mania 5·35; and in dementia only 1·04 per cent. Excess of urea was seen most frequently in melancholia, least so in dementia. Lithic acid and lithate of ammonia were likewise observed, most frequently in melancholia, and least so in dementia; lithic acid being, in all three forms of insanity, of much more usual occurrence than lithate of ammonia. Crystals of triple phosphate were met with in dementia, at the rate of 25 per cent.; in mania 23·21; and in melancholia 6·66 per cent. Crystals of oxalate of lime were seen in every fourth case of melancholia, or at the rate of 25 per cent.; in mania, the proportion was 17·85, and in dementia, only 2·08 per cent. Muriates occurred at about the average of 13 per cent. in all three forms of insanity. Muco-pus globules were most frequent in mania, viz. 17·85 per cent., whereas in melancholia, they were at the rate of 10·, and in dementia of 7·72 per cent. The last, or fourteenth, table contains a condensed summary of the whole.

	Colour of Urine.	Acid Urine.	Sediments.	Specific Gravity.	Serous.	Urea. Excess of	Lithic Acid.	Lithate of Ammonia.	Triple Phosph. Crystals.	Oxalate of Lime.	Carbonates.	Muriate of Ammonia.	Muco-Pus.
Mania	High	80·35 per cent.	87·50 per cent.	Between 10·21 & 10·30	5·35 per cent.	33·92 per cent.	89·46 per cent.	19·64 per cent.	23·21 per cent.	17·85 per cent.	16·07 per cent.	14·28 per cent.	17·85 per cent.
Melancholia .	High	80·00 per cent.	100 per cent.	Between 10·21 & 10·30	7·50 per cent.	47·50 per cent.	47·50 per cent.	32·50 per cent.	6·66 per cent.	25 per cent.	30 per cent.	12·50 per cent.	10 per cent.
Dementia ...	Light	63·54 per cent.	54·16 per cent.	Between 10·11 & 10·20	1·04 per cent.	16·66 per cent.	13·54 per cent.	1·04 per cent.	25 per cent.	2·08 per cent.	34·37 per cent.	14·58 per cent.	7·27 per cent.

Foreign Body in the Bronchia of a newly-born Infant.—The following case was related at the séance of one of the professors at Marseilles. A child, two months old, was seated upon the lap of its mother, who was engaged in preparing beans for dinner; suddenly he was seized with a convulsive cough, recurring at intervals, and always succeeded by a perfect calm. A physician was called, who, on examination, found the following condition of things: face pale; countenance fixed and expressing great uneasiness; respiration difficult, and detected by the motion of the nostrils; no fever; and nothing revealed by auscultation. The slightest movement induced a suffocating access of cough, and the child leaned forward and opened his mouth wide, as if for vomiting. Various hypotheses were suggested as to the nature of the case, and, in the meantime, leeches, an emetic, and blisters, were prescribed. A foreign substance being finally suspected, tracheotomy was performed, but it proved unsuccessful, as the child soon after died. At the autopsy, a large white bean was found at the bifurcation of the bronchial tubes; it was swollen, and surrounded by pus and false membrane; the lungs were hepatized.

Improved kind of Ligature.—Dr. Thomas M. Lee observes, that in using the common double ligature, he has oftener than once experienced a good deal of inconvenience when the patient was unsteady, from the necessity for some manipulation, in order to ascertain which were the ends of the one, and which of the other thread. It has occurred to Dr. L. that the apparatus alluded to might be rendered much more perfect by having one-half of each thread intended for a double ligature dyed black, while the other half is allowed to retain its original light colour. The advantages of this plan are, that after the needle is cut away, the two ends of each thread can be easily seized and tied, saving the anxiety which delay occasions. The difference in colour at once distinguishes the one ligature from the other, so that there is no need for pulling at the different ends to gain this information. The preparation of this thread is very simple, one half only of each hank having to be dipped into the dye. The hank thus prepared may then be cut through, either at one point in its circumference where the black and white parts meet, or at two, viz. in the middle of the white, and again, in the middle of the black part.

Absence of the Urinary Bladder in a Man.—Dr. D. Ross Leitch had an opportunity of of examining a singular case of malformation of the above nature in the person of a man, æt 39. The man died after fracture of the femur extending into the knee-joint. The body was slight and effeminate; there were beard and whiskers, but only a few scattered hairs on the pubes. His voice had been weak, and rather shrill. There was no appearance whatever of a penis. The man declared that he had once possessed something of the kind, but nothing remained to corroborate the statement. As in the case of Highmore's boy, referred to by Dr. Duncan in the first number of the *Medical and Surgical Journal*, "all was entire and smooth," from the orifice of the ureters to the anus. The testes were small but natural, similar to the cases mentioned by Desault, Knox, and others; they were contained in folds of skin near the pubes. As is almost universal in these malformations, the bones of the pubes were separated to a considerable distance from each other, the intervals being filled up by a broad strong ligament; the symphysis and descending rami of the pubes were wanting. By separating the acetabula and thighs to a greater distance than usual, this had rendered the man's walk less firm than common, and produced a rolling from side to side. The anus was thrown so far forwards that there could scarcely be said to be any perineum. A slight umbilical scar was visible low down in the hypogastric region, about an inch and a half to the right of the urinary orifice. There was no trace of the corpora cavernosa, or appearance of a scrotum. The epididymes on both sides were very observable, terminating naturally in the vasa deferentia, which, after a brief course, expanded into the vesiculæ seminales, and there, with the prostate gland were attached to the posterior part of the conjoined ureters. Certain minute orifices, into which a bristle could be thrust, appeared near the mouth of the urinary passage; and these seemed to have given exit to the seminal fluid. The *left* kidney was early natural; the pelvis, however, was more capacious than usual, and the ureter on that side was slightly increased in its calibre. In the *right* kidney, the cortical substance had disappeared, and the organ pre-

sented the appearance of a globular membranous bag, the sides of which, as well as those of the corresponding ureter, were thick, firm, and condensed in their structure. The *right* ureter was twelve or fourteen lines in diameter. About an inch and a half from its termination on the surface of the abdomen it was contracted so as to perform the office of a valve. Muscular fibres could be traced at this portion of the ureter. Though the urine had continually dribbled away from the unfortunate patient, he declared he was able to expel it from time to time in considerable quantities: there is little reason to doubt the statement, for the right kidney and ureter were found after death filled with urine. Dr. L. thinks it probable that the water which continually trickled from the orifice came altogether, or in great part, from the *left* kidney, there being nothing in the corresponding ureter to obstruct its flow, but that the valve at the lower part of the *right* ureter enabled him to retain the urine in that distended canal, and the capacious pelvis of the kidney for some time, and that, by the pressure of the abdominal muscles, the membrane at its valvular portion was so far overcome as to permit the discharge of the collected fluid. It seemed to be a very curious and admirable instance of the ingenuity of nature in compensating original deficiency of structure. There was not the slightest trace whatever of the urinary bladder, but the ureters terminated at their point of junction on the skin above the pubes. There was abundant proof that the man had possessed the sexual appetite. It is also mentioned that the banns had been three separate and distinct times proclaimed at the parish church, between him and a woman who was attached to him.

Danger of Hydropathy.—Dr. M. Hall says, there is *one* aspect in which the administration of the several measures included in hydropathy should be especially viewed. They all require great powers of re-action in the patient. Now, if there be inflammation, and especially if there be congestion, of an internal organ or organs; if, from such or any other cause, the blood driven from the surface do not regain its former diffusive course, fatal consequences may ensue. This observation applies especially to dyspepsia, gout, and rheumatism, with their peculiar diathesis and disposition to remove and fall on the internal organs; to diseases of the heart, with its series of visceral congestions (see the Gulstonian Lectures for 1842, p. 48); to diseases of the lungs, the liver, and intestines; and to disease of the kidneys.

Pyromania.—The following description of pyromania is from the Fifth Annual Report of the Crichton Royal Institution for Lunatics, at Dumfries. A more rare variety of alienation is pyromania, or the tendency to incendiarism. It seems a modification of the blind impulse to destroy. While traceable to perversion of the will and sentiments, it may be provoked by malice, revenge, or other motives common to the vicious and unsound mind. A very large number of the cases which have been most carefully examined have occurred in mere children, or extremely young females, who, when able to explain their conduct, have assigned no more intelligible reason than a desire to witness a conflagration. The disease is occasionally epidemic or imitative, affects various individuals unconnected by consanguinity or intercourse in succession, and spreads desolation and terror over a whole country. This should be kept in view when such acts are investigated judicially, for madmen may be mingled with anarchists; or the act of the malicious or rebellious incendiary may have suggested a similar course to the excited imagination or distempered propensities of the pyromaniac. At precisely the same time in 1830, when such devastation was committed in England by rick-burners, bands of young women perpetrated similar ravages in France without apparent object or design. They were regarded and treated, and perhaps wisely, as lunatics. The involuntary propensity to burn is generally associated with bodily disturbance, an undeveloped constitution, and mental imbecility, but it is not necessarily so. It may likewise be the element of a mind combining strong intellect, serenity, and self-control. It has occasionally been developed as the last atrocity of despotism, or the wildest erraticism of genius. If combined with the monomania of pride and superstition, the patient burns a palace or a cathedral: if with the tendency to suicide, he casts himself into the fire; if goaded by imaginary insults or injuries, the property of an enemy is selected; but if the desire be blind, insensate, impetuous, the destruction is indiscriminate. Persons labouring under the impulse not merely disregard life, they act as if it were invulnerable, and caress the flame they have produced, and almost invariably and anxiously watch its progress. One of this class, who was not a suicide, has been observed to handle ignited coals as if they were harmless, and, after setting fire to a sofa, sit quietly down upon the burning cloth as if to court immolation. Another inmate, who originally manifested her derangement by attempting to destroy farm produce, still, upon all favourable occasions, consigns her dress to the fire, without regard to the value of the article or to her own comfort, and obviously derives intense gratification from the brilliant flame which she has produced. This woman, although passionate, and so irrational as to recognise in her fellow-patients former friends and acquaintances, disguised as females, is acute, cunning, and perfectly conscious of the culpable and dangerous nature of her irresistible propensities."

TRANSACTIONS OF LEARNED SOCIETIES.

Royal Medical and Chirurgical Society, June 14th, 1845.—Cæsar Hawkins, Esq., in the chair.

Large opening into the anterior part of the Urethra, caused by sloughing, and attended by considerable loss of substance, successfully treated by operation; with remarks and illustrative drawings, by F. Le Gros Clark, Assistant Surgeon to St. Thomas' Hospital.]

The author commenced his paper by pointing out the difficulty of curing urinary fistulæ in general, but much more especially so those which are situated in that part of the urethra anterior to the scrotum. In illustration of those remarks, he quoted the opinions and experience of Professor Dieffenbach, who had been repeatedly foiled in his attempts to cure even small fistulæ, in this situation, before he ultimately succeeded. The author then refers to the various modes of treatment which had been adopted in these cases, and gives the palm to that which consisted in renewing the lost substance by a plastic operation. This part of the subject was further illustrated by reference to Professor Dieffenbach's practice, as the author acted in his own cases on the principle laid down by the Berlin Professor, though he deviated in his mode of carrying it into effect: this principle consists in extending as much as possible the surface, by which adhesions might take place.

The subject of the operation in the present instance was a wine porter, who had permanent stricture, for which he was operated upon by Mr. Clark in July last; but being of intemperate habits and not very good constitution, he had acute inflammation of the testicle, followed by sloughing of the scrotum and penis, which, after the healing process was completed, left an aperture in the urethra, one inch and a quarter in length, occupying a small portion of the scrotal division of the passages, and extending forward for a considerable distance anterior to it. The following were the steps of the operation for the closure of this opening: a small inverted portion of skin was first dissected out from the scrotal extremity of the fistula, four incisions were then made, two of which extended downwards and outwards, over the scrotum, and the other two upwards and outwards, on the side of the penis. A lateral flap was thus marked out on each side, which was thus dissected up, and the two being brought together, *surface to surface*, over the fistulous opening, were maintained in that position by lateral splints of leather, and sutures passed through the latter and the skin. A semilunar incision was then made on each side, to relieve the anticipated tension when swelling came on, and a full sized gum elastic catheter, which had been passed prior to the commencement of the operation, was left in the bladder. Adhesion took place throughout the whole extent of the flap, except at two points, one being at the scrotal extremity of the fistula, the other between the lateral supports, these were freely touched with caustic, and soon closed. A small portion of the margin of one flap sloughed. The operation was performed in November, and at the present date, (June 10th) the patient continues to pass his water freely and in a full stream. There is no contraction of the penis or any part of the passages, and the cicatrix is scarcely visible. The perineal opening still allows of the occasional escape of a drop of urine.

Mr. Le Gros Clark said that rather more than three months had elapsed since the operation was performed. He had recently seen the patient, who could pass water very freely, and did not labour under any inconvenience; there was scarcely any appearance of his having undergone an operation.

Mr. Blizard Curling observed that he had seen the patient the day before, and fully substantiated the statement made by Mr. Le Gros Clark. The opening in the perineum, however, was not quite closed, and a few drops of urine occasionally distilled from it during micturition, but there was scarcely any attendant inconvenience.

Mr. Acton understood the author, as attributing the stricture and subsequent fistulous opening to the employment of injections; if this really was the opinion of Mr. Le Gros Clark, he (Mr. Acton) should be sorry to let such an opinion pass without comment, particularly as it was one opposed to the first authorities on the subject, and might, if uncontradicted, again give currency to the belief, that stricture is caused by injection rather than by the chronic inflammation the injections are used to cure, a doctrine that formerly made our profession view these remedies (however mild they might be) with great suspicion, and still existed as a popular prejudice in the mind of the public. The case related this evening further corroborated the opinion expressed in his treatise on venereal diseases, that no one operation was sufficient to remedy fistula in these situations, but that we can only expect a perfect cure after repeated attempts with the knife and caustic, as happened in several cases he witnessed in the practice of M. Ricord.

Mr. Le Gros Clark in answer to the objections raised by Mr. Acton respecting the production of stricture by the employment of injections, observed that he had found, as the result of his own experience, that stricture was caused, not by the proper and methodical use of injections, but by their employment, by patients acting on their own suggestions, and undirected by professional skill. On this subject he was anxious to learn the opinion of surgeons generally. They were now very rarely used in the public hospitals, and certainly not at St. Thomas'; he (Mr. Le Gros Clark) believed that their non-employment was owing to the dread of injuring the urethra.

Mr. Cæsar Hawkins inquired of Mr. Acton whether in M. Ricord's cases, the parts were brought together by the edges, or by the surfaces, as practised by Mr. Le Gros Clark.

Mr. Acton stated he had seen various plans put in practice, but by far the most successful was that related and delineated in the Clinique Iconographique (to be found in the library of the society) where M. Ricord made an artificial opening into the membraneous portion of the urethra immediately behind the bulb, and allowed the urine to pass off by means of a gum-elastic catheter fixed in this opening; he then pared the edges of the fistula situate anteriorly to the artificial opening, and brought them together by means of pins on a bougie introduced into the urethra; the fistulous opening closed after several applications of nitrate of silver, and in three months, the artificial opening was allowed to heal, which it did most speedily.

Mr. Davis, of Hampstead, made some general observations in opposition to the doctrine referring the production of stricture to the use of injections and remarked, that when he was a *surgeon*, he had seen some thousand such cases in the army, which were treated by injection, as it was important to have the men on parade again as soon as possible.

He had been in the habit of employing the infusion or tincture of digitalis or opium, in a diluted condition, and had derived great benefit from their judicious use, and had never heard of the occurrence of stricture in any case, although some of the men had been under his notice for years afterwards.

Mr. Le Gros Clark remarked that in his communication, he alluded to the injudicious use of injections as a cause of stricture, and he did not think that his observations would bear the interpretation put upon them.

Mr. Davis, of Hampstead, explained that the remarks he had made were intended to bear a general acceptation, and were not directed specially to Mr. Le Gros Clark's paper.

Mr. Le Gros Clark referred the occurrence of stricture, from the use of injections to the production of inflammation of the testicle, the inflammation extending along the cord by contiguity of stricture to the urethra.

Mr. Stanley spoke of the exceeding value of the paper, with respect to the details of the operation, and said that he had no doubt that many cases that had fallen under his notice, formerly, would have been cured, if the principle on which it should be performed, had then been properly understood. He had not had the opportunity of applying this principle himself in any case to the urethra, but had done so in several cases in deformities of the face, and that successfully. In one of these cases, that of a girl, who had lost part of the under lip, he formed the flap from the skin of the neck, not in accordance with the principle of the Taliacotian operation, but by partial dissection and pushing up of the flap. The cut edges of the part gradually assumed the appearance of the natural red lips. Many such cases had occurred, bearing out the principle.

Mr. Brooke remarked that the only two points in which this operation failed of being completely successful, would probably have been obviated, if the bead suture (a description of which he had already laid before the public) had been applied. In this patient, vitality was evidently at a low ebb, and a very slight degree of pressure would therefore suffice to arrest the circulation, and produce a slough. The pressure of the bits of leather and platina wire made use of in this case, appeared to have been sufficient to produce the effect. And a similar unfavourable result followed the application of a pin and figure of 8 ligature to the perineal opening; this is easily accounted for by the constriction to which the portion of integument included between the pin and ligature is necessarily subjected, as soon as that vascular distension takes place, which precedes the process of reparation.

Account of a Case of Dissecting Aneurism of the Aorta. By Theophilus Thompson, M.D.

A gentleman, forty-five years of age, having suffered for some hours from a severe attack of abdominal pain, resembling ordinary colic, after slight exertion fell down in a state of syncope. The author, who was called in, found him apparently insensible, with a pallid countenance and cold extremities, but able to swallow. Brandy was freely administered, but an hour elapsed before the pulse became perceptible either at the wrist or in the cardiac region. The pulse when first observable was only fifteen in the minute, but in a few hours, under the use of stimulants, it gradually rose to a hundred. The urinary secretion was suppressed. With the restoration of the circulation the intellectual faculties in some degree revived. Two days after the fit of syncope, the circulation again became feeble, the extremities cold, and the patient's countenance assumed an appearance of wildness and weakness characteristic of exhaustion. With these indications of internal hæmorrhage, an extension of dulness on making percussion in the præcordial region excited the suspicion that blood was effused into the pericardium. Death occurred suddenly after some considerable muscular efforts.

On making an examination after death, the pericardium was found distended with blood, which was partly coagulated. The cellular envelope of the aorta from which the blood had transuded into the pericardium, was charged with coagulum. Half an inch above the free border of the posterior valve of the aorta, was a sigmoid rent, nearly an inch in extent, passing through the internal and part of the middle coat of the vessel. The blood having found a new channel between the layers of this middle coat, had extended upwards, around various portions of the circumference of the vessels to the carotids, downwards as far as the origin of the renal arteries, and the intruding current of blood had torn away the inner and middle coats of some of the intercostal arteries from their attachment to the aorta. The substance of the left ventricle was thicker but less firm than natural. The calibre of the aorta, although larger than usual, presented no special or partial dilatation. The inner arterial coat was throughout delicate and brittle; that of the aorta exhibited atheromatous deposits in almost every part, excepting that in which the laceration had occurred.

The bladder contained a little urine, which became opaque on boiling. The kidneys were slightly granular. The author attributed the fatal event to the action of an hypertrophied heart, excited by pain, alarm, and exertion, on the lacerable arterial tunics, this friability being probably owing to imperfect nutrition, the consequence of disease in the coronary arteries. He referred to the somewhat rare occurrence of escape of blood into the pericardium, without rupture of that membrane, as explaining the gradual failure of the powers after partial amendment; and considered that phenomena such as those present in this instance, although somewhat obscure, were sufficient to authorise a suspicion of the real nature of the injury.

Dr. Jeaffreson observed that cases of this kind were far from common, and related one which had occurred to him a short time before, and had formed the subject of a medico-legal investigation. The patient was a strong powerful man, thirty-two years of age, who, when returning home, was attacked with severe pain across the abdomen, extending to the back—the chest and heart being quite free from it. The man was supposed to have been poisoned by a biscuit which he had picked up in the street and had eaten, but of this there were no symptoms. The pain he endured was very agonising. Dr. Jeaffreson was inclined to look upon the case as one of spasm caused by the passage of gall-stones. The pulse was not changed in tone or character. Towards the evening symptoms of exhaustion came on, and he died the next morning. On examining the body after death, the pericardium was found to be greatly distended with blood, and the arch of the aorta resembled a large aneurism, that appearance being produced by a considerable effusion of blood between the coats of the aorta, extending along the arch to the thoracic portion for about six or seven inches in length. The immediate cause of death was an opening in the aorta, just in front of the aortic valves, by which the blood was effused into the cavity of the pericardium. Throughout the case there were not any symptoms of derangement of the circulation. The pulse, which was perfectly natural, ranged from eighty to eighty-four beats in the minute. He (Dr. Jeaffreson) had omitted to state that the pain which the patient complained of, was accompanied by vomiting.

Mr. Cæsar Hawkins remarked that the greater number of cases of this disease, affecting the thoracic aorta, generally came under the care of the physician. In one instance which had fallen under his own notice, the aneurism, however, was seated in the abdominal aorta. The patient, a female, had been admitted into the hospital under his care, with gangrena senilis, affecting one of the toes; about a fortnight before death she complained of severe pains in the abdomen, where, on examination, a large pulsating tumor was discovered. She died of exhaustion, caused by the extension of the gangrene, which ultimately reached the groin. When the body was opened after death, there was found a dissecting aneurism of the abdominal aorta, in which the inner membrane had been separated throughout its entire circumference to the extent of about six inches, but the canal was not diminished in size, on account of the dilatation which the outer-coat had undergone. The edges of the apertures, of which there were two or three, were exceedingly rugged.

Dr. Jeaffreson observed that in the case which he had described, there was not any atheromatous deposit in the aorta, unless it were in the early stage. The coronary arteries were also free from disease, but the heart was hypertrophied.

Dr. Peacock stated that when he was in Edinburgh, three cases of this disease had fallen under his notice. Two of these had been published in the *London and Edinburgh Medical Journal*, and the other by Dr. Henderson. Two of these were similar to the cases, the details of which had been narrated that evening at the meeting; in the other there was a new canal formed, and the disease appeared to have been of long standing, although, generally speaking, it is of a few hours' duration only. The symptoms by which the formation of this peculiar form of aneurism may be recognised, occur very suddenly. The patient is seized with severe pain and syncope, then rallies for a time, and afterwards dies very suddenly. In the majority of cases, dissecting aneurism affected the thoracic aorta, and generally near the arch. He (Dr. Peacock) had, however, met with a case in which the abdominal aorta was the part of the vessel which was diseased, and the first case which had been published of the disease, which occurred in the practice of Laennec, was located in the abdomen. The cavity forming the aneurism is situated between the lamellæ of the middle coat, and not between it and the outer coat: of this there are several cases on record, and there is a preparation in the Museum of the College of Surgeons illustrative of this point. In a case which has been described by Mr. Guthrie, the aneurism is situated between the lamellæ of the middle coat, with the addition of a few fibres of the outer coat, and the same thing has occurred in the case under the notice of the Society.

Dr. Maclonghlin had met with a case of dissecting aneurism in a soldier, many years ago, the details of which were published in the *Glasgow Medical Journal*. The patient was suddenly seized with syncope, from which he was roused by frictions with opium and other stimuli, and apparently recovered. Two days afterwards he had a tooth extracted, when he screamed out, and fell down apparently apoplectic. He died twenty minutes afterwards. On examining the body after death, the pericardium was found to be full of blood, and the aorta ruptured near its valves to the extent of two-thirds of its circumference. It was a perfectly clean cut. The aorta was ecchymosed, and there was a separation between the external and middle coats. The aorta was otherwise sound. The preparation was sent to Fort Pitt Museum, at Chatham. The symptoms diagnostic of rupture in this case were—fainting, severe pain, and sickness.

Case of Circumscribed Arteritis. By Robt. Druitt, Esq., Surgeon, London; communicated by Wm. Fergusson, Esq.

The patient, a young man, aged 22, subject to a violent and irregular action of the heart, following acute rheumatism in his youth, during recovery from an attack of acute dysentery, found, on awaking in the morning, his right arm cold and benumbed, and he was unable to keep it warm. The author, on visiting him, was unable to feel the pulse at the wrist, and found the arm cold, and flaccid. The subclavian and axillary arteries beat most forcibly, and on tracing the latter downwards, he found that, at one spot, just where it becomes brachial, it felt enlarged and solid, and was tender to the touch. Down to this spot, which was about an inch in extent, the pulsation was as strong as possible; but here it ceased abruptly, and below it, there was not the least pulsation in any of the arteries of the limb. The arm was kept wrapped up, and at rest. During the ensuing week, the warmth, feeling, and strength gradually improved. He afterwards went out of town for a fortnight, and on his return, the circulation was completely restored. The axillary and brachial arteries were pervious throughout, and the pulse was beating, as at the other wrist. The author believes the cause of the above related phenomena

to have been a sub-acute inflammation of a portion of the artery, with effusion of lymph from its inner surface, and slight coagulation of blood. Cases of this disease are not uncommon, but the author never met with a case in which the effusion was absorbed, and the canal of the artery restored.

Mr. Cæsar Hawkins observed, that there was a deficient point in the detail of this case. Mr. Druitt had mentioned the cessation of pulsation in the artery, and its restoration a fortnight afterwards, but he had omitted to state the precise date at which the return of pulsation in the vessel took place.

The next and last meeting of this present session, will be held on Tuesday, the 24th inst.

NOTICES TO CORRESPONDENTS.

A pressure of business, (which our readers will easily give us credit for this *week) postpones all our Correspondence to our next number.*

THE MEDICAL TIMES.

SATURDAY, JUNE 28, 1845.

Postquam omnis res mea Janum
Ad medium fracta est, aliena negotia curo,
Excussus propriis.

HORACE.

During the last six weeks we have been compelled to hear a great deal about some imaginary aggregate meeting, in which the two great performers (positively for the first time playing on the same stage) were to be G. J. Guthrie, F.R.S. and Thomas Wakley, Esq., Coroner and M.P., a statesman recently rather celebrated for his hundred and fifty pound character. Country meetings were to be held: requisitions to be signed: a public breakfast to be eaten in the real presence of half a dozen hypothetical Members of Parliament—the four thousand four hundred members of the National Association were to disappear like snow under a tropic sun; and a sudden *coup de main* carried on by a united profession was to make the twenty-four pure surgeons of Lincoln's Inn Fields open their doors forthwith to the General Practitioners *en masse*! The whole scheme, of course, was a bubble—a "delusion, a mockery, and a snare." The advertised compact between Guthrie and Wakley was a suggested falsehood—a tolerated forgery; the professed aim was not only (and to the schemer's knowledge) impracticable, but *unsought* and *unhoped for*; the co-operation that was chosen was knowingly a co-operation without any agreement in principle; in short, except in the miserable prompting motives, the whole affair was a series of false pretences, supported by false statements, cozening and deluding the profession by every artifice of a scheming and active unprincipledness. And what is the result? One false pretence has become exposed after another: hundreds of misstatements have met their public refutation; the party's motives have got unmasked: the principles and aims become a little less darkly understood: the county meetings are not being held; the country support is not being given; the names are being withdrawn from the requisitions; the cry of "hoax" and "swindle" is distinctly heard on all sides, and the schemers think it necessary, under the best excuses they can invent, to postpone and postpone indefinitely their hypothetical meeting and supposititious breakfast!

In one word the bubble has burst; The requisition is a non-entity: G. James Guthrie, F.R.S., will never take the chair; there will be no public breakfast nor aggregate meeting; the imposture has got turgid, and has broken; a lesson to respectable men, let us trust, not to serve even indirectly the dirty purposes of unprincipled people in the poor hope of having their own purposes served in turn. There is a help that may contaminate without serving: and to use dishonour as a tool shews no fastidiousness of virtue, or no affluence of resources.

With the well-known principles of Mr Guthrie and his minority, and with the well-known practices of Sir B. Brodie and the majority, there must have been some audacity in any individual at this late hour of the day holding out the lure of enfranchisement in the College of Surgeons as a motive for rejecting the actual offer of a New College of our own. The very first official document that appeared from the College demonstrated the absurdity of the impudent fallacy. Did the arch-schemer, therefore, cease to blow the bubble? No. What others were taught by the new document he knew well before; and therefore to prop up his delusion he resorts to another false pretence, and publicly affirms that the official statement that proved his project a hoax, was a hoax itself! and while affecting to give the whole document, omitted, when publishing it, the *parts* which showed that it was *unanimously* agreed to, and that Mr. Guthrie was one of its supporters!

Again. Mr. Guthrie states publicly in a letter his own opinions on what he would propose; and though very guarded, his letter clearly enough shows that he is prepared to do nothing that the Profession now would not reject with disdain.

What does his new self-selected colleague? He passes by the letter as if it never existed! He advertises G. J. Guthrie, F.R.S. is the chair, at an indefinitely postponed meeting—but *dares* not publish to the dupes whom he *expects*, the avowed sentiments of that G. J. Guthrie, F.R.S.!

But enough: the profession have seen sufficient to be put on their guard; and if the *corporate* opponents of the new Colleges succeed, as *they perhaps may*, in flinging out the amended bill for the session, and, therefore, for ever—it will be for us to maintain in organised union, so large a confederation that in February next we may be prepared to introduce our own bill by a M.P. of our own choice, and have a reasonable assurance of pressing it successfully on the attention of Parliament.

Sed bona, si quis
Judice condiderit, laudatur Cæsare, si quis
Opprobriis dignum latraverit, integer ipse?

HORACE.

Mr. Wakley's unfortunate character has been again placed under the care of the law. The hundred and one times that the sickly, debilitated thing has had the benefit of legal attendance and advice appear to have proved inefficacious. The malady is as threatening as ever; the patient as weakly. The character, therefore, has been again compelled to consult the legal doctors—and comes away in worse plight than ever. The fate of the poor thing seems hopeless. A remedy is of the first necessity, yet the constitution's weakness makes that remedy the highest danger. It is every whit as ill off now in 1845, under the scientific attendance of Mr. Jervis against an attack of that appalling malady the *Medical Times*, as when twenty years since, under the skilful treatment of Mr. Denman, it had to struggle against the dire visitation of the Hope Insurance Company. Action follows action, and the work is only to be be begun again. Even the House of Commons ceases to be a secure asylum. It contains its Wodehouses. The very stones cry out against that worst fated of public things—the character of Mr. Wakley.

And what has Mr. Wakley got by his last attempt at legal doctorship? A fair balance sheet giving a strict account of the profit and loss would be interesting.

The libel was certainly not a mealy-mouthed production. It spoke of Mr. Wakley as never letter spoke of any other public man. Without condescending to enter on any nice *minutiæ*, it stated broadly circumstances and inferences, which, by comparison, proved Wilkes to be *veracious*, and Chartres a man of probity. The fact of its being *legally* a libel was not disputed. To prove the charges spoken of as prevailing was not attempted. It would have been as wise to essay to bind the winds. It was legally impracticable. As the Lord Chief Baron remarked too, no apology was made, no excuse offered; the *Medical Times* appeared in the court letter in hand, yielding nothing, denying nothing, flinching in nought. In so many words it said, "we stand upon the letter: judge between it and Mr. Wakley's character. Damages you must give. How much, we trust with secure confidence to your estimate of the character!" Well. A jury of *gentlemen* to whom a hundred pounds is much the same thing as as many shillings to the ordinary components of a common jury, and *therefore* chosen by the plaintiff—appraise the worth of the character so grievously aspersed. The plaintiff says his injury is £2,000. The judge says that being admitted to be a libel, handsome damages should be given to suit the high position of the plaintiff as a Coroner and M.P.: the plaintiff's counsel says the aspersions will last for ever unless very high damages are given: the jury—the *special* jury—retire, and after three hours appraise the character at £150, an accident alone preventing its being £100! And this is called clearing character! Why the six daily (not to speak of weekly and provincial) papers that republished the libel would have charged more money for inserting it as an advertisement!

A Leicester journal falsely asserted, that the Duke of Brunswick was mistaken for a swell-mobman, and wrongfully taken to prison. In the next number, it corrected its error, and apologised for the inaccuracy. The Duke, not satisfied, sought damages, and the jury, after hearing an eminent counsel against his claim, awarded him £200! Compare with that libel the letter of Vindicator—with that journal's apology—our unyieldingness—and how different the estimate an English jury forms of the character of Mr. Wakley, M.P., and Coroner of Middlesex, and the Duke of Brunswick! Mr. Wakley, M.P., and Coroner of Middlesex, asks £2000 for his character; a jury of his own selection, under a judge of his own preference, appealed to by one of the first counsel of the country, give him £150! We trust he is satisfied; if so, we assure him we are quite content. So small an enjoyment to a quarter so rarely visited by such things, could be begrudged only by a *very* vindictive enemy. We repeat, we are content; we never spent a hundred and fifty pounds more to our satisfaction.

Though we thus look on the result of the trial as a virtual triumph, we still persist in our opinion, that the letter was, in the first place, most improperly made the subject of litigation, and that, when made the subject of litigation, it was most improperly, in the second place, made the subject of a peculiar and a wrongful form of procedure. The question between Mr. Wakley and the Profession was one not to be decided by a costly court of law, hampered with special technical rules, excluding a mass of evidence, which alone could enable the arbiters to give an honest judgment. The Pro-

fession is the only fair and competent tribunal, and when Mr. Wakley withdrew his character from their jurisdiction, he in so many words impugned their fairness, or his own standing. Are medical men acute? Are they just? He says they are. Why not, then, have trusted himself to them? We were ready; why was not he? Because the law was *more* than fair—favorable! To any plaintiff willing to risk his character on its operation it offered no small advantage. First, the law calls any questioning of the personal worth of a public man a libel. Anything is a libel which has a *tendency* to bring a man, good or bad, into contempt or ridicule. The theory of law, that existed before free discussion existed, exists still; judges must administer it as they find it; and it is notorious they will allow the Press to denounce no abuse which their own laws have by any accident allowed to pass unscathed. What, then, could we have done with the letter of "Vindicator?" Give up the author's name? That would hardly suit *our* idea of editorial honour. Mr. Wakley may deliberately betray, through a miserable pique, a name confided to him; he may jealously keep what was pledged to be destroyed, and publish what was solemly promised should be suppressed: but a communication confided to us—at whatever hazard—is safe. High danger or low—the writer's name was sacred.

Should we, then, justify? We had no such power. The law-books speak of such a power—but it is a power—as the first mob says in Coriolanus "we had no power to do!" The writer's charge was that Mr. Wakley had a bad repute; and that certain facts or accusations should be inquired into. What says the law? What says the judge? Public journals must make no such demands: you must not talk about *inquiring* until you have first *condemned!* Prove first that the rumours are true—and then you may, when all matter of inquiry is settled, say that there is cause for investigation! We infer no blame to the learned judge. It is not his place to see error in the law. But then we might have pleaded "Not Guilty." But *not guilty* is a plea which excludes every consideration but two: was there a publication? and was the thing so published a libel? And of what avail would it have been to deny a fact self-evident, or a conclusion of law notorious? Had Mr. Wakley proceeded by "*criminal information*," he would have lost all these advantages, and we should have escaped such inconvenience. The profession would have had the benefit of his affidavit, (made before the very judge that conducted as counsel his case against the Hope Insurance Company) swearing that the rumour, or charges, or whatever they were groundless; he would have undergone, under oath, the defendant's examination; we should have been at liberty to plead that the inquiry mooted was mooted for "the public service" by a late reformed act, and if it turned out that that was a valid defence, our expences must have been paid for us. The process adopted was so *luckily* circumstanced that we could not escape without paying at least our own part of the expenditure!

It need not be said that a hundred actions like this—undertaken avowedly in a vindictive spirit "to ruin the *Medical Times*, if it cost him a thousand pounds"—would not be worth a farthing on the point of clearing character. The tax that public men pay for their ambition is searching scrutiny, and the public will not demand enquiry one iota less because a peculiarly placed M.P. says, "*there is to* screen me a rigid theory of law, which I will stretch at all hazards to keep me uninvestigated." Every vain effort but loudens the cry it would suppress, and wherever there is a journal, there there is an echo catching the sound, and reverberating its demand with augmented force, and necessitating at last a compliance which would have been graceful had it been voluntary.

In parting with this subject, it gives us much pain, amid all the kindly assurances of support and good feeling surrounding us, to express a word of complaint against the report of the trial as given in the *Times* newspaper. By some accident the notice of the proceedings, arising from the preliminary motion to change the scene of the "inquiry," did not appear in the *Times*, although it was duly published in all the other morning journals; and by some similar cause, the report of the trial in the *Times* intimates a bias for the plaintiff we have looked in vain to find in any of the other journals. The *Times* omits the declaration of Mr. Jervis, that the *Medical Times* had a "very large and considerable circulation;" attributes to Mr. Healey at least two phrases, or sentiments, which he never used, and generally exhibits a feeling which we should call biassed and prejudiced, if in a respectable *employe* it must not have originated in inadvertence. We cannot, however, but regret, even the inadvertence of a journal whose extensive circulation makes each error so mischievous.

Est huic diversum vitio vitium prope majus,
Asperitas agrestis, et inconcinna gravisque
Quæ se commendat tonsa cute, dentibus atris;
Dum vult libertas mera dici, veraque virtus.
HORACE.

ABERNETHY in his forcible and blunt way declared that the best thing that could be said of an operation, even when most successful, was, that it was a reproach to surgery—necessary, perhaps, but still a reproach. And it cannot be doubted but that the still existing frequency of operations, taken in their best aspect, is no small impeachment of the progress of medical science. The most deplorable circumstance however about operations is not so much the pain or mutilations they cause, as their fatality to human life. There is nothing, after all, more deplorable in the history of medicine than their unsuccessful result as a general rule. The ingenuity and industry of surgeons have had their best field for exercise in the concealment of their operative misfortunes. The records of their ill successes is, fortunately for them, a matter of autobiography, and the instances in which we meet a candid narrative of failure are as rare as might be expected from the awkwardness to a professional man of a self-condemnation. A clandestine survey of the private memoranda of a *successful* operator would present his utility to society under a very different aspect to that in which he is ordinarily viewed. It would be tragical as a narrative, and comical as a contrast.

Of all diseases, probably there are none that have been the cause of more fatal operations than aneurism. The ligature of the surgeon has been almost as fatal as the noose of the hangman. It would be interesting to know on how many this operation has been performed; it would be still more interesting to ascertain how few it has saved!

The mischief that has thus arisen often proceeds from no error of principle in the procedure itself. Good operations fail hourly from unskilful management; and perhaps the severest ordeal that the very best operative procedure can undergo is a marvellous mechanical perfection, heedless of every other consideration, and blind to all those medical precautions and appliances on which, after all, must depend the patient's chance of a happy issue. When the "*reproach*" of *surgery* becomes, through some peculiar manual dexterity, the *distinction* of the *surgeon*, the temptation to display, without reference to time, place, or occasion, is irresistible—especially when the universal eye of the public looks our way and asks for something brilliant.

It was not fair in us, we admit, but when we heard that Mr. Liston had hurried down to Portsmouth to Mr. Seton, providently taking with him an experienced operative assistant, we could not suppress a kind of conviction that before Mr. Liston's return there must be an operation. The well known skill of that gentleman suggests in his presence magical qualities to an operation medical men could never for a moment soberly think of in connection with the ordinary agencies of scientific medicine. All the perilous vicissitudes of the knife are forgotten in the fascinations of his mechanical adroitness!

Still it would have been as well perhaps if Mr. Liston and his assistant had returned from Portsmouth as they went, leaving Mr. Seton in happy ignorance of the operative brilliancy of which Europe so loudly speaks. At all events, it is clear to us, that if he essayed an operation at all, it should not have been the more daring and perilous one he instinctively adopted, of tying the external iliac, but that of securing the small vessel actually wounded. Though the peculiarity of this case is, that we are dependent for the whole of our facts on those who are personally interested in giving such a version as may suppose them to have exercised the most prudent and skilful discretion, yet, considering the formidable character of the operation, as well as the shock to the constitution so lately received by the patient, it is difficult to conceive how, if Mr. Liston had the same idea on the diathesis of Mr. Seton, as his assistant Dr. Potter, that he could have adventured so hastily to tie the external iliac.

Dr. Potter tells us:—"It may be well, in the first place, to premise that the patient was remarkably fat, particularly considering his age, (about twenty-eight or twenty-nine;) that he was understood to have lived very freely, and taken little exercise for several years; that his constitution was described as delicate and impressible; and that, when indisposed, he was always observed to be easily lowered by treatment."

In such a case, to risk such a procedure was indeed to peril the repute of the operator and the character of the operation. The extent of the wound on so fat a subject, would be a source of immense constitutional irritation; and no reasonable man could doubt that the peritonitis which supervened was almost inevitable. The chance of a happy issue was scarcely one per cent. Two such shocks in the narrow range of nine days was a visitation which, under no contingency, could fail to be fatal. The vessel wounded was so small that it is nameless in anatomical science. For seven days there had been no return of the hemorrhage, nor was any tumour visible; and though during the two subsequent days, a pulsatory swelling exhibited itself, it hardly appears to have been greater on the second than on the first day (on the 29th than on the 28th of May.) On the following day there seems to have been considerable doubt whether any increase had taken place during the last twenty-four hours; for Mr. Liston, when speaking of the matter, does not venture to affirm any such

opinion, and hesitatingly states—that "some" thought it had enlarged during the preceding night; the inference being obvious, that he and others did not think so. It was clear, therefore from the whole history, that the femoral artery, or, in other words, *any* important vessel, was not wounded. Nay, a pulsation was even felt in the femoral artery on the distal side of the tumour, which every surgeon knows could not have been noticeable had there been a wound of any consequence in that vessel. Our conclusion, then, is clear from the evidence of the operators and their assistants, that if an operation was necessary, more time might have been taken to consider what it should be, and that when the resolution was taken, there would be the utmost reason for doubting the propriety of preferring the plan of penetrating through five inches of fat to tie so important a vessel as the external iliac, (thereby exposing the patient, and *such* a patient, the almost inevitable invasion of peritonitis,) to the humbler, less brilliant but safer procedure of endeavouring to secure the small wounded vessel, the source (as Mr. Liston's immense experience should have told him) of the whole mischief. We see no one circumstance which called for a precipitate operation. The tumour was a *circumscribed* aneurism; we have every thing but evi- dence to show that it was not extending; i had only appeared for two days; the patient was improving in health; he is described not only as strengthening, but as cheerful and hopeful of the results. A few days' delay would have introduced no new element of danger; in that time nature might have shown a beneficial agency in the closure of the wounded vessel, and in any case symptoms would have exhibited themselves which would have enabled the surgeon to have decided with something like a reasonable judgement on the nature of the operation to be performed. In fact, Mr. Liston seems to have thought nothing of the very probable danger of mortification of the limb, of the peritonitis which carried off the patient, or of the reiterated shock to the nervous system, in his anxiety about an effusion which never might take place, and which might have been warded off by means far simpler and safer, if less brilliant or less extraordinary. We can only understand the moderate reasonableness of Mr. Liston's course of action, by supposing him to have laboured under an error, he would be the first to disclaim, namely —that notwithstanding every physiological proof to the contrary, the femoral artery had been actually wounded. But, of course, it is not our duty, and far less is it our inclination to dilate on errors which may happen even to the best practitioners, and which are every day happening to the most eminent men in the profession. It is not given to all men to possess all the excellencies of the medical art, and the self-confidence which will assume any such perfection, is most of all likely to fail at a critical conjuncture. Diagnostic ability is almost the last perfection which comes to the Medical Practitioner. It is not because Lady Flora Hastings' liver was mistaken by a Court Physician for an impregnated uterus, or because an aneurism of the carotid artery was punctured by some "pure" of the North London Hospital for an abscess, that we are to indulge in any violent invectives against the Surgeons or Physicians, whose good fortunes it is to have attained high positions amongst us; the true use of such examples after teaching us the propriety of caution in all matters that concern human life, is to impress upon those who aim at a good organisation of the Medical Profession, the absolute necessity of each Practitioner being forced to master all the branches of the Profession before he be allowed to practice specially in any. The mere operator, ignorant or careless of constitutional treatment, gives his patients but one half the appliances of medicine, and must constantly lose by treatment the triumphs he has been winning by operations. And in the same way the Physician, ignorant of midwifery or surgery, who in complicated cases of disease, unwittingly perils reputations and endangers lives, with the more extended education which befits his calling would have been the saviour of both.

> Dicer docendum adhuc, quae censet amiculus, ut si
> Caecus iter monstrare velit; tamen aspice si quid
> Et nos, quod cures proprium fecisse, loquamur.
>
> HORACE.

WE have only a few more observations to make concerning the *modus operandi* of tea, together with a word or two about the popular use of the herb, and then farewell to the subject. We fancy our patient readers responding with Othello, "To that we say, amen." At a meeting of the Wesleyan Conference some few years back, an American Preacher who was famous, or rather infamous, for making speeches of an unbearable length, terminated one of his orations somewhat abruptly. The President, scarcely crediting its conclusion, asked with the anxiety of a prisoner awaiting a verdict,—"Mr.——— have you finished your speech?" "I have Sir," said Jonathan. "Praise God from whom all blessings flow!" was the thankful response from the chair. We are almost afraid, the prolixity of our discourse (and its promised finish) will obtain a similar ejaculation from those who have had the equivocal relish of reading it. And yet we are not without a hope that we have conveyed a trifle of instruction, and a trifle more of innocent entertainment.

It will be remembered, we said in a previous article, that the action of tea is in some sort intermediate between that of digitalis and opium—affecting the heart like the one, and the brain like the other. The former we have discussed at sufficient length, the latter we need be only brief upon. We anticipate being told that it is too much of a paradox to say the same thing is at one and the same time both a stimulant and a sedative. Not at all, if the sense in which the words are used be rightly understood. We have already proved that tea is a sedative—now to prove that it is a stimulant, and so liken it to opium. Stimulants are of various sorts; some derive their properties chiefly from an acridity which they possess, and their action is for the most part local; pepper, mustard, and such like things, are of this class. Yet even these, though their action is chiefly local, that is, confined to the particular spot they touch, sometimes produce an effect upon the nervous centres. We have known a large mustard plaster bring on convulsions, and have also seen an unusual mirth and intellectual elevation follow its use. Its internal administration has been succeeded by complete drunkenness. A man in a fit of jealousy called at a druggist's shop for an ounce of arsenic. It being suspected what was his object, he was served with prepared chalk. He went home, mixed, and swallowed the expected poison, and then revealed the calamity to his wife. The surgeon who was sent for, in the absence of a stomach pump and a more available emetic, gave the man a large dose of mustard. It did not make him sick, but in course of half an hour he was thoroughly drunk. In the meantime it was discovered what his potion had been, and he was left to recover *sua sponte* from the effects of the mustard. Dr. Paris relates the case of a man, who after long fasting, was intoxicated by a basin of soup. It was probably well seasoned. In these cases, and in other such, the action is, properly speaking, local, and any further, manifestation which it may make, will depend upon the organ to which it is directed. If to the spinal chord, agitation of the limbs, convulsions, or paralysis, may follow; if to the brain, an increased or diminished intelligence may be the result. Tickling the ribs or the armpits for instance, excites in some people a venereal passion, others it depresses almost to faintness, a third it sends to sleep, and a fourth it intellectualises and keeps awake. A celebrated novel writer was in the habit of having the soles of his feet tickled to produce a lively state of imagination. It is said of a luxurious Roman Emperor, that he had the same operation performed during sleep to produce agreeable dreams.

Other stimulants, such as alcohol and ammonia, act in two ways, locally, upon the parts they touch, and *specifically*, by absorption or through the nervous system, upon the brain. Tea does not belong to either class; it more resembles opium, and is yet an intellectual stimulant in a greater degree than even this marvellous drug. De Quincey, as is well known, claims for opium an influence upon the mind which he says is neither intoxicating nor stupifying. Had he been better acquainted with it, he would say with us that it can not only elevate the mind in its proper sphere and mode of action, but that it can also, and just as easily, rouse that mind into frenzy, or lock it up in stupor. Tea, however, does no such thing. Though it can give a temporary strength and freedom to intelligence, especially to memory, imagination, and judgment, it never, or at least very rarely and only in peculiarities of constitution, gives rise to anything like inebriety. It is the purest of stimulants, and seems, if such were possible, to act upon the mind almost without making the body subservient to its purpose, just as a beautiful idea, springing momentarily, and in magnificence, from the suggestion of sight, hearing, or smell, seems to be rather a self creation of the brain, than a borrowing, variously magnified and modelled, from the testimony of the senses. But in spite of the plausibilities of "transcendentalism" and "pure reason," we know that such things are not our heritage, and we must accord to Byron more credit for poetry than philosphy when he affirms:—

> The beings of the mind are not of clay;
> Essentially immortal, they create
> And multiply in us a brighter ray
> And more beloved existence:—

The stimulant action of tea appears to be directly upon the brain, of course through the medium of the nervous system; but what stimulation it imparts to the *body*, would seem to be merely a *reflection* from the *sensorium*. When it relieves a tired body it is by first relieving a tired mind, but it imparts no solid vigour and gives no permanent strength. It is just a *a refreshment* of power, not a *re-enforcement* of it. It does, what under other circumstances, *mind itself*, by its inherent action and effort, might do. The favourite son of a very severe father was crossing a rapid stream on horseback, his parent awaiting him on the opposite side. The stream bore him along, against the efforts of himself and his an'mal, until at length he ceased his exertions, and cried despairingly, "Oh, I shall drown! I shall drown!" "If you do, sir," shouted the father, "I will flog you to death!" Instantly he recovered his self-possession, and with renewed strength struggled with the tide,

and finally reached the shore in safety. There is a familiar anecdote of a gentleman, who, in walking with his little boys, had taken them farther than he intended, when they became so tired and footsore, that he doubted whether he should be able to get them home. At last it occurred to him to cut each one a long stick, and calling it a horse, put him astride it. The device was perfectly successful, for every feeling of fatigue was directly forgotten in the novel play of imagination. Thus, also, is it accounted for, that the tedium of a march should be relieved by the fife and drum, and that national music, as happened to the bagpipes at Waterloo, should put fresh life and courage into soldiery surrounded by desolation and slaughter.

We have dwelt thus particularly upon this department of our subject, for we know it to be a question, not only with the public but with the profession, what may be the physiological action of tea? One says it is a stimulant, another says it is a sedative, and we say it is both. We have shown that its secondary and long continued action is of a depressing nature, and that the primary one is excitant; not the excitation of alcohol, which affects first the spinal, and then the cerebral, nervous centre, but one of an opposite kind, influencing first the *intellectual*, and the *physical* after and through it. As might be expected, the action has little permanency in it, and a repetition of the dose does not long ensure a revival of the effect. After a time it ceases to stimulate, and produces a languor greater even than that which it was originally intended to correct.

Tea has become so customary a beverage with all classes of the community in this country, that instead of being considered, what it really is, a luxury or a medicine, it is classed amongst the *necessaries* of life. The generality of its use will be understood from the fact, that during the past year upwards of fifty millions of pounds weight were consumed in Great Britain alone—involving a taxation of nearly four millions sterling. And all this is for the gratification of appetite and the production of pleasurable sensations! We are neither healthier nor happier than our ancestors of the middle of the sixteenth century, amongst whom tea was first introduced by the Dutch, and considering what good and what harm it has done, perhaps Patin was in the right for calling it "l'impertinente nouveauté du siècle." At least we are certain that there is no correspondence whatever between the cost of the article and the service of it. We are no advocates for limiting an expenditure by which government profits, when such expenditure is not inconsistent with the health and welfare of the public at large. Such things are necessary to the substantiality and well-being of powerful and commanding states. Nor is it of import how the rich may gratify their appetites or at what cost—they are seldom serious sufferers of personal indulgence. It is the poor who are most concerned in the relation of outlay and income—and for them it is our duty to feel in the various questions of political economy. To supply a necessity by fair means, is to answer one of the fundamental duties of existence—to gratify a costly inclination, when the sacrifice is greater than the requital, is to commit a sin. On the part of the rich man, the sin is against his fellow creatures—on the part of a poor man, the sin is against himself. The personality of an offence is no lessening of its enormity—both are answerable alike to the tribunal of common propriety. A man who *earns* the money which maintains him, owes to himself the duty of rightly appropriating it. In the economy of self management, it becomes him to consider how he can best apply it to the purposes of his health, strength, and comfort. Every farthing which he squanders in unholy pleasure or living, his conscience will tell him is an evil, and society will not be backward in confirming the verdict. But drunkeness and gambling are not the solitary sins of expenditure. They perhaps carry a greater evidence of immorality upon their very face than some others, but apart from the vices to which they lead, they are not in themselves a greater vice than many other forms of what is considered a venial indulgence. He who wants a shilling for some worthier purpose, is just as much in error if he squander it in the indulgence of tea as in the indulgence of spirituous liquor. If the money be *thrown away*, it matters little what may be the medium of the loss. Poor people will often deprive themselves of a meal of meat, a *necessity* and a *service* to them, for "a dish of tea," a mere effeminating luxury. It is the most expensive item in the pauper's housekeeping book, and perhaps the most useless. We are not arguing against poverty finding an indulgence where it can—we would it were found oftener—but we would have the gratification to be consonant both with appetite and wealth, and a wish that the poor may realize the double enjoyment, has alone prompted us to say these homely things.

MEMORIAL ON MEDICAL REFORM FROM BRISTOL.

To the Right Honourable Sir James Graham, Baronet, &c. &c.

The memorial of the undersigned Practitioners in Medicine and Surgery residing in Bristol and its neighbourhood—showeth,

That your memorialists are desirous of thanking you most cordially for the very patient and considerate attention you have been pleased to give to their representatives, the Committee of the National Association, whilst laying before you the just claims of so large a majority of the Medical Profession. That they have observed with satisfaction the proposed alterations in your amended Medical Bill, especially those referring to their Corporation. And lastly, that they are most anxious to convey to you their earnest hope, that you will on no account be prevented from passing the Bill into a law during this present session of Parliament.

Signed by 47 Gentlemen.

MR. WAKLEY, M.P. *v.* THE MEDICAL TIMES.

A meeting of members of the Medical Profession was held at the Crown and Anchor on Monday, June 23rd, W. Griffith, Esq., late lecturer on surgery to the Westminster Hospital School, in the chair.

It was moved by W. B. Costello, Esq., M.D., of Golden-square, and Wyke House, Brentford, and seconded by R. Knox, M.D., F.R.S.E., Lecturer on Anatomy and Physiology, Edinburgh, Member of the National Institute of France, &c.;—

"That at no time was there greater need or a more pressing duty than now, freely to discuss the claims to confidence of the public men seeking to direct the *interests* of the Medical Profession, and that Mr. Wakley in taking advantage of a peculiar legal technicality to assess the editor of the *Medical Times* in damages, for publishing a letter, enquiring into his (Mr. Wakley's) claims to public confidence, has improperly endeavoured to repress in the Medical Profession the exercise of the right of free discussion, and that it is the sense of this meeting that his conduct, in this particular, is strongly condemned by the whole course of his own editorial management, both as relates to men and measures, and taken into account in connection with his recent vacillating and factious conduct in reference to the Medical Bill, calls for the unqualified reprobation of every member of the Medical Profession."

Moved by G. Hume Weatherhead, M.D., senior physician to the Royal Free Hospital, seconded by H. J. Mc Dougall, Esq., late House-Surgeon to the University College Hospital :—

"That this meeting deem it their duty appropriately to give effect to these opinions, by assuming for themselves and the profession, the whole responsibility of the recent actions against the editors of the *Medical Times*, and thus explicitly declare their judgment as regards a procedure necessarily incomplete in reference to character, and unfair and oppressive in its operation."

Moved by J. Ryan, Esq., M.D., Professor of chemistry to the Polytechnic Institution and the Royal Naval College, Portsmouth, seconded by G. D. Dermott, Esq., lecturer on anatomy and surgery to the Charlotte-street School of Medicine :—

"That it is the duty of this meeting, in behalf of themselves and the Profession, publicly to acknowledge their obligations to the untiring assiduity in promoting the interests of the medical public, to the enlightened views advocated and developed in regard to the re-organization of the profession, to the general treatment of the question of medical polity, both in a literary and ethical sense, and to the superior tone in which the business, the feelings, and the wants of the profession have been administered to, by the Medical Times; and that to testify our special admiration and confidence in the editor of that *Journal*, the Profession is hereby called upon to defray, by subscription, the expenses incurred through the recent legal proceedings instituted by the editor of the *Lancet*."

It was resolved that circulars should be forwarded to the members of the profession, calling for their co-operation in the object of the meeting, and that the resolutions should be extensively advertised.

Subscriptions will be received by the Treasurers, W. Griffiths, Esq., 31, Lower Belgrave-street, Pimlico, and R. B. Knowles, Esq., 59, Arlington-street, Camden-town; by the Honorary Secretaries; by Mr. Renshaw, the medical publisher, Strand, and by the publisher of the *Medical Times*. *

W. GRIFFITHS, Chairman,
W. B. COSTELLO, } Honorary
JOHN FOOTE, } Secretaries.

Solubility of Oxide of Lead in Pure Water.—At a meeting of the Chemical Society, a paper by Lieut.-Col. Philip Yorke, 'On the Solubility of Oxide of Lead in Pure Water,' was read. It is from this property that leaden pipes and cisterns become dangerous, when the water which fills them is soft and pure. The lead, however, which the water takes up may be removed by filtering the water through paper; a circumstance which has been explained by supposing that the oxide of lead is not really dissolved in the water, but merely suspended in it. The author, however, shows that the oxide of lead is taken up by the substance of the paper and combines with it, from an affinity such as subsists between the same metallic oxide and cotton fibre; the last taking the oxide from solution in lime-water, and lead being often fixed as a mordant on cloth for dyeing in this way, according to the statement of Mr. Crum. He finds also that the power of the filter may be exhausted, and that, therefore, it would be unsafe to trust to the action of a filter to separate oxide of lead from water for an unlimited time.

Dr. Hodges, of Gay-street, Bath, has been elected physician to the Bath General Hospital, v. Dr. King, who has resigned.

* The subscriptions already received amount to upwards of £30.

REVIEWS.

Geology for Beginners; comprising a Familiar Explanation of Geology, and its Associate Sciences, &c. By G. F. Richardson, F.G.S., of the British Museum, &c., London: Longman, Brown, Green, and Longmans. pp. 624, 12mo. Second Edition. 1843.

Works, whose avowed object is the communication of elementary knowledge in the various sciences, are very rarely written in the style of pure and luminous simplicity adapted to the weak intellectual powers, or the limited attainments, of the young or uninitiated. The lecturer or the scribe upon such subjects, should constantly bear in mind, that the majority of persons who listen to his oral, or peruse his written lessons, are utterly ignorant of the science to which those lessons relate, and, consequently, should accommodate the food to the edentulous jaws, and delicate stomach, of those whose wants it is intended to supply. Strong viands may suit the vigorous digestion of the adolescent, or the adult in science; but the intellectual aliment of the babe obviously requires to be administered in the form of pap.

In this respect, however, we have little fault to find with Mr. Richardson, or his Geology. Although not exactly coming up to our rigorous standard of the method and simplicity which should, we think, characterise such productions, it certainly makes a nearer approach to that standard than any elementary treatise which, for many years, it has been our lot to peruse.

It forms one of the great attractions and advantages of the study of geology, that a knowledge of divers of the most interesting and delightful branches of natural science is essential to a profound and philosophical comprehension of its phenomena and mysteries. Impressed with this important truth, Mr. Richardson has, very properly, after giving four chapters, for the most part occupied with definitions, explanations, the literature of geology, and other introductory matter, devoted the five succeeding chapters of his book to rapid, but, in general, masterly and correct sketches of mineralogy, physical geology, fossil conchology, fossil botany, and palæontology, or, more correctly speaking, *palæozoology:* * since, as we have elsewhere observed, the term palæontology, taken in its literal signification, obviously comprehends the doctrine of both fossil animals and fossil plants.

This, however, is not the only instance in which Mr. Richardson, while displaying an intimate acquaintance with German literature, exhibits a deplorable lack of knowledge in the construction of the dead languages. The author, who, into a second, and of course, revised edition of a scientific work, can introduce such terms as a *phenomenu*," and "a *strata*," and employ "*animalculæ* as the plural of animalculum,† should surely descend, for awhile, from his lofty communings with the high Dutch, to acquire a more accurate knowledge, or retrace his well-nigh obliterated recollections, of the structure of the more vulgar languages of Greece and Rome. The remaining twelve chapters of the work—it consists, altogether, of twenty-one—are devoted to "a concise description of the various geological formations, and of the phenomena of science as developed in the creation around us."

Interesting and valuable to the student of geology, as is the information presented in the five chapters which comprehend an outline of the auxiliary sciences, much additional and most useful matter might have been introduced into them, by dint of a little condensation, without any increment of the dimensions of the volume. But Mr. Richardson is not only a lax and verbose, but a very careless, writer. In justification of this censure, we proceed to quote from his chapters on fossil conchology (concholithology?) and palæontology (palæozoology) the following extraordinary announcements:—

"The animals,"—our author is here alluding to the combiperous mollusca—"as they respectively possess one or two (adductor) muscles, are termed *unimusculosa* and *bimusculosa;* as the *unimusculosa are all fresh water shells*, and the *bimusculosa all marine*, this part alone is sufficient to determine the character of the shells, and, consequently, when they occur in a fossil strata (state?) the origin, fresh water or marine, of the strata in which they are found." Page 277. Again, "The star-fish is a *genus* of animals of the *molluscous order*." Page 382.

Is Mr. Richardson, then, ignorant, or can he, in an unlucky hour, have possibly forgotten that many of the testaceous animals which constitute the family of the *mytilacea*, ranged, by all the first-rate zoologists of the present day in the bimusculose or dymyasian sub-class of class, *conchifera*, inhabit fresh waters; and that the *ostracea*, confessedly belonging to the unimusculose or monomyasian sub-class, are almost exclusively denizens of the ocean?

And, secondly, let us inquire what relationship, with the solitary exception of their belonging to the great invertebrated division of the animal kingdom, exists between the radiated asteriad, and the far more highly organised members of the sub-kingdom, not "order," of the *mollusca*. In fact, the *asteroidea* constitute the first order of class, *echinodermata*. This class stands at the head of those arranged in modern systems of zoology, under the sub-kingdom, *nematoneura;* which is widely separated from the lowest class of *mollusca* by the intervention of the sub-regnum of the articulated animals.

Blunders, such as these, which a glance into the admirable production of Professor Jones,* or even into one of the alphabets of "Alphabet Rennie," would have sufficed to correct, are utterly unpardonable. They would disgrace an elementary treatise of the lowest grade and pretensions. Perpetrated by a highly-gifted and popular writer like Mr. Richardson, who professes to instruct the young and ignorant, and has, in some respects, deservedly acquired their respect and confidence, they call for exposure and denunciation more than ordinarily flagrant and austere. The indolent and vitiated state of the intellectual system, which they indicate, can only be remedied by severe discipline. Our sentence, therefore, is that Mr. Richardson, author of "Geology for Beginners," abstain, for at least three calendar months, from the accustomed stimulant of praise so lavishly supplied to him by shallow critics and blind admirers; that he abjure, for ever, the society and worship of those wicked syrens, the Muses; and that he swallow, at least three times a week, the drastic, but salutary dose, now administered by his unknown doctor of the "Medical Times." This prescription failing of success, we shall pronounce the author's case hopeless, and abandon him, in despair, to his cruel fate and still more cruel friends.

An appendix, of some dozen pages, is occupied by sundry poetical effusions, of the peculiar merits of which we are very incompetent judges. The freaks and the phantasies of poetry may be all very good in their way; but, mixed up with the profound researches, the solid parts, and the vigorous deductions of science, they form, in our opinion, a very discordant and most unprofitable, or even noxious compound. Deeply do we regret, both for the sake of Mr. Richardson and his readers, that the space, so unbecomingly taken up by the fantastic display of his "Waulkes," and his "Taulkes," his nautical cephalopods, and his coral caves, was not devoted to an extension of the very slender and defective glossary, which terminates his work. Many of the scientific terms, as, for example, *heterocereal*, and *homocereal*, which the author has employed, do not find a place in that glossary; nor, strange as it may appear, is the deficiency in those, and in many other instances, supplied by a reference to the well-meant, but assuredly very humble dictionary of Dr. Humble.* Mr. Richardson cannot, in these days, require to be informed that the sailing feats of the Nautilus, which constitutes the subject of his second poem, have long been proved to be as mere a fiction of the distempered brain of some crazy poet, as the hyemal submersion of the swallow, and the extrication of the barnacle-goose from the cirrhopod which yet bear the name of their imaginary offspring.

A third edition of the "Geology for Beginners," if it have not yet seen the light, must necessarily, ere long, be called for, carefully purified and expurgated from the various blemishes and defects † which, in the severe, but liberal spirit of independent criticism, we have taken the liberty of pointing out, as derogatory to the character, and injurious to the success, of an otherwise excellent and valuable publication. We shall hail with pleasure the improved edition, confer upon it the honourable, because unbought and disinterested testimony of our high approval, and recommend it to our host of readers as the best elementary work which has hitherto appeared upon this subject in the English language.

* See Medical Times, current volume, page 46.

† In some part of his work, to which we cannot at this moment refer, Mr. Richardson talks of "*microscopic animalcules.*" Now, as the definition of an animalcule is an animal so minute as only to be discoverable by the aid of the *microscope*, the employment of the epithet, "*microscopic*," is obviously superfluous.

* A General Outline of the Animal Kingdom. 8vo. London. 1841.

* Dictionary of Geology and Mineralogy. *Second* edition, with additions. 8vo. London: 1843.

† At page 218, ninth line from the bottom, a glaring blunder occurs; and *bronchiæ* for *branchiæ*, in page 517.

T. WAKLEY, CORONER AND M.P., VERSUS THE MEDICAL TIMES.

DAMAGES LAID AT £2,000; VERDICT £150

On Friday, June 20, this important case came before the Lord Chief Baron of the Court of Exchequer, on a writ of inquiry, to assess the damages done to Mr. Wakley's character by an article which appeared in the *Medical Times* of the 25th of January last, under the signature of "Vindicator."

A special jury having been struck, at the prayer of the plaintiff, and duly sworn,

Mr. Bramwell opened the pleadings.

Mr. Jervis, Q. C., rose and said that he appeared on behalf of Mr. Wakley, the plaintiff in this case, and who came to complain before them of a libel which it was his duty to designate as at once disgraceful and scandalous. It was not necessary for him to introduce his client to their acquaintance as an individual well known to them all for the able discharge of his duties, both as a coroner and a Member of Parliament. The office of coroner was one of the few magistracies that yet remained open to popular election, and if Mr. Wakley had strenuously endeavoured to maintain, in full integrity, the privileges of that ancient office, he (Mr. Jervis) was quite sure that he would meet on that account no ill feeling from the jury he was addressing. To his politics he had no occasion to allude, except that they had secured him the confidence of the very large constituency of Finsbury, and that, in an arena like the present, it was always their boast that, whatever be the politics of the parties entering it, they were never considered for a moment as having any influence on their decision. Politics did not intrude themselves in the jury-box. For himself he could say that, though not of the same politics as Mr. Wakley, it in no way affected him in his personal relations or good opinion, or other Members of Parliament. But, beyond Mr. Wakley's public functions, he could speak of him in another capacity—as a distinguished surgeon, and the editor and proprietor of the *Lancet*—a fact which, he thought, might explain perhaps why this libel had appeared. The defendant, Mr. Healey, he regretted to say, was a member of that profession to which he (Mr. Jervis) had the honour to belong; and the other defendant, Mr. Weathers, was a member of a profession equally respected and honourable—he was a surgeon. They were the proprietors of a journal having a very considerable circulation, addressed to the same profession to which plaintiff belonged, and were of course answerable for the contents of that journal. They were more

especially answerable, for he believed it would be thown that they were the authors of the libel, or as least one of them. Mr. Wakley, having the highest respect for free discussion and the liberty of the press, had applied to the printers and the publishers to ascertain the author of the libel; they had refused to give his name, and, therefore, he supposed the defendants were here, ready to avow themselves the authors of this disgraceful libel. He believed one of them to be the author, and, unless assured to the contrary, would still entertain the same opinion. The libel now complained of appeared in the *Medical Times* of the 25th of January, and was of so gross and improper a character, that the plaintiff felt that he had no choice, for his own sake and that of his friends, but to proceed against the defendants. The defendants, if they could not have proved a justification, had the opportunity of pleading Not Guilty to the declaration; but they had adopted no such course. They had allowed judgment to go by default, and they did not deny that the publication was a libel—they made no attempt to show that it was justifiable in point of fact; and he (Mr. Jervis) was instructed to say that his client felt the more injured by the course the defendants had thus thought proper to pursue. Under ordinary circumstances, this case would have gone before the Under-sheriff, to be tried before him and the usual jury, but the plaintiff was anxious to have the presidency of one of the judges of the land, and to vindicate himself as publicly as he had been attacked; and, therefore, had the plaintiff applied and obtained permission for a trial before the Lord Chief Baron and a special jury, whose duty it would be to assess the damages which, in their opinion, the plaintiff was entitled to as a reparation for the injury inflicted on him. The libel was printed in large type, and he would now proceed to read it to the jury.

PROPOSAL FOR MR. WAKLEY'S TRIAL BY A JURY OF GENTLEMEN.

(To the Editor of the Medical Times.)

SIR,—Should I even seem unnecessarily to obtrude on public attention a name which professional delicacy, or your own editorial tact, would veil in silence, I will yet appeal to your sense of right—even *to* an enemy—to favour me with the full insertion of my proposal. It aims, Sir, to free a worthy man from hideous accusations, or sever from a high-minded profession a gangrenous member, perilous to its safety. The moral dandy, fastidious enough to veto to my just charity her only means of discharging her duty, will shew a very miserable estimate of the *worth of character*. In the hospital of diseased reputations there is such a thing as mistaken diagnosis; and that surgery—as Wakley will admit—is the truest cruelty which, to a man in his position, would deny, through an unmeaning delicacy, the most probing examination.

I know, Sir, of the common verdict of society, that the character which has not received Mr. Wakley's own care, is unworthy that of all others; and though I am singular enough to entertain a different opinion, it will not impair my argument to admit that his reputation has been so far trodden under foot, that while, on the one hand, it can be cleansed, if redeemable at all, only by a vigorous effort, his utility and comfort of conscience, on the other, are gone for ever if that effort be not made—*and successfully*. For, Sir, most unquestionably, as a great career was denied him by Nature, so a good one is cut from him by his character. Befoulment has so far eaten into his name, that had he the best of desires and greatest of energies, it would kill both. A moral leprosy encrusts it, each day spreading, which repels each *good*, and keeps aloof each *prudent* man. True, the taint may be only imaginary, but public opinion gives vigour to the hypothetical virus, and makes it as deadly to himself, and those around him, as though it were real. The fatality of public opinion—even, alas! if erroneous—offers him, abroad, a social lazar-house, alike infected, and infecting; touching ever, and tainting for ever.

For the honour of the profession, therefore, and for his own case, I beseech you, Sir, not to interpose any personal hostility you may have between him and his full vindication. You are surely too powerful not to be able to afford your enemy an ample justice; and if charity have weight with you, a moment's retrospect will shew how much of mischief he has been forced to do, and of good to relinquish, solely through the detestation of his character.

The London College of Medicine was, in its origin, a glorious affair. It had every thing in its favour but one—the hostility of Wakley. He unfortunately gave it his support—and it perished! *He* lost his battle; his companions *their* honour. By blunder, or crime, or doom mysterious, each associate to this day has imputed to him imposture, or roguery. The accounts were not formally balanced; wherefore, honourable men were looked on as felons! A breath bears evidence of crime, when corroborated by acquaintanceship with Wakley!

The British Medical Association followed. The same history, the same end! If Wakley could not raise it, he generously lent it, when raised—his name. It glistened under the light of his countenance with a sickly radiance, thawing off like snow under a tropic sun! The treachery of the one faculty "scheme," followed other schemes to ruin; bill, bill, to ridicule; member, member to secession, till all that is now left of this once influential society, is a hybrid M.D. and apothecary of Dulwich, prefigured and described by Pope

> "Eternal smiles his emptiness betray,
> As shallow streams run dimpling all the way;
> Whether in florid impotence he speaks,
> And as the prompter breathes, the puppet squeaks."

He is, of the British Medical Association, the unmutilated tail still left to tell that once Kilkenny "cats"—and dogs—dwelt there!

Last came the Medical Protection Association. I saw with wonderment how suddenly, in power, and wealth, and wisdom, this young society, obeying your call, sprung to being. It was born a man; it sprung, as from the brain of Jove, another Minerva, instinct with might and beauty. A multitudinous meeting, at three days' call, startled British medicine from her seat, and the world asked what shall it be—this new born giant? Surgeons and physicians—the proudest—bent their steps towards the threshold; the new popular shrine offered more promise than the old corporate idols; funds flowed in; prosperity, for once, in medical agitation, seemed our captive: but Wakley crept into the paradise, and

> "at the ear of Eve, familiar toad,
> Half froth, half venom, spit himself abroad."

Bullying the equivocally placed, darting venom at the timid, feeding the indigent with dishonoured bread, the nobly-ambitious with frothy hopes, he estranged in disgust the respectable, and enchained the rest. Strange fate of a bad name! The more he paid, the less he purchased; the more he toiled, the less he did; he worked but to injure, to ruin; his breath was a killing pestilence; power, wealth, character, association—all have gone! Surely the name of infamy is as a greedy Maëlstrom, insatiate, bottomless!

Three National Associations sunk helpless under his aid! Three hostile colleges flourishing by his opposition! Himself contemned here, spurned there, suspected everywhere! Such is the terrible result of a whole life's ceaseless action; such the awful shipwreck of a fortune steered by the helm—infamy! *What a spell, mystic and divinely misguiding, in a ruined repute! Fate will not even have good by such an instrument!*

With such a retrospect before my eye, I sincerely offer crestless and defeated Wakley (forlorn amid the ruins made by his own character) the tribute of a tender *condolence*. With all the callosity of the camel's knee, grief can yet reach his heart: he is the stoic philosopher of our century, if he can't describe a Promethean agony. Guilty or innocent, I pity either way. He has a place in society so very different from his deserts; if good—so well merited, if evil—that, for his breast to harbour an instant's joy, would be to shew the insensibility of a demon. Yes! even *goodness*, like the affection of the son-less monarch of Norman England, must be a curse; he cannot know an honest smile. His heart, for twenty years, has never fathered one! What a reason for inquiry!

I know, Sir, your deplorably adverse opinions on Mr. Wakley's past utility. You have always described him as a medical nuisance, more mischievous to the well-being of the profession than any of the grievances he has at times declaimed against; and have added your opinion, that among the public men of our time, infamy would be homeless if there had been no Wakley.* But, Sir, have you made *full* allowance, in judging his singular career, for the very singular circumstances under which he was placed? With such a drawback as his character on every effort, how *could* he have been honest, or honourable, or independent? He was to live on a public that despised or abhorred him; their contemned inferior in moral standing; how could he advise, or guide, or lead? His *rôle* was to please, not to improve; to pander, not to teach; to follow, not to lead; to halloo others' opinion, not give his own. His natural place—he knew, it Sir, well as you—was that of philosopher; his evil genius, his character, *forced* him—and he sees and regrets it—into that of buffoon. If he lauded the "One faculty scheme," yesterday, as the only panacea, to please this association, and, to pander to the liking of another, denounced it as treacherous, to-day; if to suit a taste that asked such condiments, he abused, for years, in the fish-fag grossness of the day, the apothecaries, as she-monsters of corporate imbecility; and, now, to suit a changed fancy, lauds them as the fittest of all parties to take their place at the head of a reformed medical profession; if he gave up the British Medical Association for the Medical Protection Assembly—the latter, again, for the New National Association in Marylebone; if, in short, he has supported whatever has been opposed, and opposed whatever has been opposed, like an aimless, houseless stroller, gibing at the unfortunate, jesting for the fortunate, as the price of a temporary lift from *anything*—buggy or dung-cart—going anywhere; still, Sir, the turpitude that can be logically deduced against him is a turpitude—it should be recollected—palliated by the greatest temptations. The unfortunate infamy of his repute left him without an opinion of his own. His low *character* made him low. The very bread of his public life essentially depended on his taking the clownship to any medical company that would engage him. A thorough serf—a serf in soul—he could hardly barter for the semblance of freedom.†

* * * * * * *

Now, Sir, while, on the part of Mr. Wakley, the necessity is thus extreme for a searching enquiry into these charges, so commonly made against him—it is fit that his friends remind him, that he is not in a position, just now, in which he can meet imputations—however atrocious they be—with disdain. He cannot, I deeply regret to admit, point to a spotless character, saying, "There is in it that which repels each slander!" There is unfortunately no one characteristic about him more impeached than his veracity. His word has served too many purposes to be accepted by any one who has heard the name of its utterer. Enquiry, rigid and searching, I fear, is, after all, his best interest. He generously offered to undergo it in the House, before Mr. Wodehouse; why not seek it before a tribunal of medical men? To do his enemies justice, I do not think they would be fastidious on the composition of the jury. I think I could prevail on them to empanel it of his own personal friends, provided they were of a few months' standing; nor do I think the public would receive with suspicion the verdict pronounced on him by a committee owning for its principal members even his own chums—Lawrence,

* This is a mistake of our correspondent. We never *said* so.—ED.

† Our correspondent enforces his opinions by enumerating the accusations usually made against Mr. Wakley, giving a succinct analysis of the reasons usually alleged for them. It is obvious that this part of the subject is quite unfitted for our columns.—ED.

Elliotson, McChristie, Lambert,* Costello, Hennis Green, Wardrop. It speaks well for Mr. Wakley's heart, not to have *made*, but so long to have *kept*, such friends. The profession would rely on their fiat implicitly. Again, then, I press on him a duty which may bring on us a triumphant issue! What a day of jubilee would it be that taught him he was felt to be no worse than other men! What a day of dignity for the profession that relieved it from a stigma so public, so humiliating, so damaging!

VINDICATOR.

[We would willingly have declined this clever letter, as—among other reasons—giving importance to a subject long without any; but the appeal to our sense of fairness was irresistible.—ED.]

The learned counsel then resumed:—The low vulgarity of this letter was equalled only by its stupidity, and the notes of the editor were, if possible, more scurrilous than the letter itself. Mr. Healey, whom he should call the writer of this letter, until he had distinctly denied it, had invited Mr. Wakley to come before a tribunal of gentlemen, and Mr. Wakley now responded to the appeal. The defendants left it to be inferred that Mr. Wakley was a personage of the lowest and most infamous character, so that any ruffian might imagine the plaintiff guilty of any imaginable offence that could be included in the vague and general tenor of the imputations; and this was the more poignantly felt by the plaintiff, for, as the pleadings now stood, the enemies of Mr. Wakley would be able to say, "In these imputations there is, you may be certain, a great deal more than meets the eye!" He earnestly and confidently trusted, therefore, that the jury, considering the character of the libel and the position of the plaintiff, would give such high damages, that, whenever this libel should again be referred to, and one party might say, "What charges were made against Mr. Wakley!" others might be able to answer, "Aye, but see what heavy damages the jury awarded for them." The person who would publish such a libel as this—he would not say out of personal malice, but of a motive still more contemptible—advancing the interests of a rival journal—would care little about the truth or falsehood of what he published, and no man would be safe from attacks of this kind, if the jury did not award damages adequate to the greatness of the offence. The learned counsel concluded an eloquent address, which evidently produced a very strong effect on the jury, by saying that, from the defendants' appearing in person, it was very possible that they meant to use the greater liberty usually conceded a defendant by the court, for the purpose of attacking more fiercely the character of the plaintiff. In that case, he (Mr. Jervis) should claim a right to reply, and he was quite sure that such a course would only be heaping coals of fire on their own heads.—The proprietorship was then admitted.

MR. JERVIS proposed to put in the reply of the publisher of the *Medical Times* to an application made to him for the name of the author of "VINDICATOR."

Mr. HEALEY objected that such evidence would be irregular. The proprietors were the defendants in this case, and there was no proof of their knowledge of the application or the reply. The letter was really of no consequence, for he believed it merely expressed the writer's ignorance on the point of authorship; but he objected on the score of its irregularity.

The LORD CHIEF BARON, after reading the letter, decided that it could not be admitted.

This being the plaintiff's case,

Mr. HEALEY addressed the jury. He said that, as a novice in public addresses, he felt no small embarrassment in following the learned counsel, Mr. Jervis; and that if he did address the jury personally in this case, he could assure the jury it was through no such motives as those so hastily attributed to him by Mr. Jervis. He would say, it was not his will that so much consented, for he felt that in the course of his observations, vital as they might be to his own future prospects, he should have often to claim the indulgence and forbearance of the court, and that his principal confidence in the just and favourable decision he expected lay principally in the jury supplying, by their own thoughts, the deficiencies of his inexperience, and carefully giving full effect to the many favourable suggestions arising out of the case which he might forget or overlook. And first, he would disclaim, utterly and entirely, any such motives, in reference to the publication before them, as had been attributed too liberally to him by the learned counsel. He entertained no malice against Mr. Wakley personally, nor against any other man breathing. He trusted he was quite incapable of ever acting on any such motive; and he rested his whole defence of this action on the broad ground that, in the libel before them, Mr. Wakley was treated solely and entirely as a public man, connected publicly with one of the learned professions of the country. This was the true issue of the whole question; and if they agreed with him in that one point, he submitted that they must concur with him in the further opinion, that it was a case for only nominal damages. The law of libel itself, though made in days when the discussion of the worth of public men was barbarously fettered to serve court purposes, always recognised a great difference from criticism of men in their public capacity, and criticism on them in their private relations. In the case of Parmiter v. Coupland (6 Meeson and Welsby, 105), it was, as pointed out to me by a legal friend, distinctly laid down that a publication may be a libel on a private person, which would not be a libel on a public character, and the right to comment openly and strongly on the conduct of public men is now legally admitted; and where, indeed, would be that liberty of the press of which we so much boast, and deservedly, if the press found in the law an inexorable censor, intrepreting, like the learned counsel, every opinion in its worst sense, and fettering, by its captious and overstrained exercise, that searching analysis of public men's worth, which is the security of our good government? Turn then, I pray you, to that letter, out of which so many distorted meanings and motives have been extracted, and ask yourselves whether it does not all through touch the plaintiff solely as a public man, and solely in his public capacity? I am sure it must have struck you, Gentlemen, forcibly, before this, that the document exhibits a perfect absence of all low and miserable scandal, of every concocted narrative of imaginary adventures, of indeed any kind of allusion the most distant to the domestic, or private, or family relations of the plaintiff. Sober or not sober, chaste or not chaste, good paymaster or knave,—these the topics, as is generally thought, of all libels, never enter for a moment into this letter. From beginning to end it has reference to public matters, public institutions, and public men—and nothing else. I defy you—reading it with your own plain sense—to say, whatever be the severities of its criticisms, that they do not refer singly and solely to the public character of the plaintiff. Nay, so strictly does this medical journal stick to medical affairs, so entirely does the letter confine itself to a consideration of the plaintiff in his public relations with the profession, that not one word of censure, or indeed notice, is given to that coronership which offers other public journals so fruitful a field of discussion and disparaging remark. In one word, this medical journal canvasses the public character of a public man in his public relations with the profession—beyond this it does nothing. The learned gentleman, with all that extraordinary adroitness which his long experience in dressing up a case for a jury has given him, has said a good deal about our letting judgment go by default. He asseverated that it amounted to an admission of the immense injustice of the letter. But, Gentlemen, how really stands the case? The learned gentleman knows better than I do, that so peculiarly is this letter situated in reference to the rules of pleading that no plea of justification that could possibly be put on the record would have been good in law. By the peculiar law of libel, which, in reference to public journals at least, cannot be altered too soon, a plea of justification would have been so much waste paper, unless we could prove not only that the charges here referred to were made—the only allegation in this letter—but that they were made truly and with entire cause. Because we say Mr. Wakley's character is widely and grievously aspersed, and should be enquired into, the law in the particular form of proceedings chosen by Mr. Wakley, says to us—You must prove not only that Mr. Wakley is aspersed, as you say, but that the aspersions are, in the thousand small particulars referred to, correct to the letter, which you do not say.* The learned counsel admits, in fact, that we could not have proved a justification by the law, and knows perfectly well, that in the case of Flint v. Pike the plea that an alleged libel was the actual substance of a trial, was successfully demurred to on the well-known legal principle that a party is not competent to notice the existence of charges unless he can substantiate beyond a quibble their accuracy. A public journal ought not in this way to have what amounts to impossibilities imposed on it by law, because it pays public opinion the compliment to notice its censures. Whether the public be right or wrong, the press cannot but notice a wide-spread and general opinion, and the law asks too much when it insists that we must prove not only what we say, that there are such charges, but also what we have not said, that they are true. Instead, therefore, of accusing me, of doing what I could not help, with submitting to a necessity I could not escape, the learned gentleman would have much better occupied your time in showing why, when two or three other courses of legal proceedings were open to the plaintiff, he specially adopted the only one that denied us a fair battle on the real merits of the case. He had just the same power of proceeding by indictment or criminal prosecution as he had of proceeding in the safe form he has chosen; but in either of those cases must have paid you the compliment of appearing in the witness-box to await your examination on the circumstances and the issue, instead of being the palpably absurd one of damages to a character which is only before us by a fiction of law, would have been the issue raised by a recent amendment of the law of libel, but which we could not have raised by *this form* of action—viz., whether the publication of a letter in a public journal on a public character was desirable on the ground of public good or not. On that issue we must have triumphed, and that issue I fearlessly assert was the only one that ought to have been raised by the publication of that letter. The plaintiff has not adopted the appropriate form of procedure the law pointed out for him in such a case as this, but he was doubtless well advised that his was not the sort of case that could be trusted to so complete and sensible an issue as the new law raised, and therefore he has sought aid against us and shelter for himself under the old unreformed law. And what stronger evidence can you have of the weakness of the case, and the small claims it advances on you on the score of damages, than the fact that the learned counsel, who is so extremely apprehensive of the irregularity in which I as a defendant may indulge, fell himself into the extraordinary irregularity of offering me to you as the writer of the letter of "VINDICATOR," without giving one particle of evidence for his extraordinary assertion. When the learned gentleman affirmed to you that I wrote the letter, and that I wrote the editorial notes attached to it, that I played commentator and correspondent in the one article, he said that which he could have proved if true; which, by not proving, is admitted to be unfounded, and which, consequently, was in every sense most unjustifiable. But, gentlemen, the needs of the case required some such help to escape the penalty of nominal damages; and, therefore, to produce an effect on you and your decision, the learned gentleman, without one tittle of evidence, is tempted to risk against me a libel degrees worse than the very libel against which he has so eloquently declaimed. Having now put the saddle on the right horse, on the question of judgment by default, and noticed that this letter considers Mr. Wakley merely in his public relations with the profession, I would submit to you that, considering the position the plaintiff must occupy

* Lambert is no more. He died in extreme poverty. He was the celebrated reporter of the case of Bransby Cooper.—ED.

in reference to the medical profession, and a public medical journal, this letter, if a libel, is at least the most justifiable libel that a jury can have to consider. I need not say that in the precise proportion in which a public man has activity and ability, in that precise proportion is he mischievous to his party, if his character lie under the suspicions that letter speaks about. Gentlemen, there is at this moment a very arduous and very important agitation going on for a better and more satisfactory organisation of the medical profession. Mr. Wakley more or less connects himself—will be connected —with that agitation. While he stands as he now stands, the medical profession will not act with him, and he is not the sort of person to let them act comfortably, if he can help it, without him. Can you not fancy, Gentlemen, that under such circumstances a medical journalist, anxious to unite all, when union will make all so much more powerful for good, may with the best motives say let a court of honour, a tribunal not legal, as the learned counsel says, but *medical*, decide on these charges. Why, the only severity, the only unkindness of such a request, would presuppose that the subject of it could not profit by inquiry—that he must be left alone, because to stir the matter would be unpleasant and disagreeable. Inquiry may not be agreeable, but a public man does not bargain for a bed of roses; it is public interest that is to be consulted, and if he shrink from the severe scrutiny his publicity involves, his best course is to retire from public life. No action for damages, in return for a request to do himself a kindness, will ever set that right which was wrong before. I am not going to waste your time in considering the worth of Mr. Wakley's character. I believe that if Mr. Wakley's character was good before the letter, it is good now, and that it is not a farthing worse or a farthing better now than it was when the letter was published. But, Gentlemen, turn to the letter, and ask yourselves what is there to injure a character that was good before? The introduction was passed over by the learned counsel as containing nothing of consequence; and on reading it you will notice a very becoming proposition, addressed to the editor with the most winning appearance of fairness. That introduction is a most important circumstance for your consideration; for I need not tell you that in the heaps of communications visiting an editor's office, he is obliged frequently to decide on the admission of a letter on the first impressions produced by the introduction. If you, Gentlemen, pen a letter somewhat differing from the views of the editor of the *Times*, or any other morning journal, what do you when addressing him but appeal directly, in the words of this letter, to "his sense of fairness even to an enemy," as an irresistible claim to the letter's admission? (Mr. Healey here read various portions of the alleged libel, pointing out the indications of fairness and truth it contained, and then continued.) The whole analysis of the letter is shortly this: "Mr. Wakley is under suspicions; he is injured, we are injured by them; let them be inquired into;" for while the writer distinctly asseverates the existence of the rumours, he as carefully abstains from saying that Mr. Wakley might not clear them if he essayed. And it is not guilt, but suspicion, that is our title to inquiry. Guilt wants *condemnation*; suspicion alone, either in the innocent or guilty, is the claim to *inquiry*. Let us suppose a case quite possible of realisation. Let us fancy that Delaney, who, after his acquittal, invited a group of friends to join him at a champaigne dinner, and shortly after exhibited himself at Newcastle as a kind of public character; let us suppose that after a long lapse of time with the public horror and disgust abated, and the grounds of belief in his guilt dissipated by years, circumstances connected him again with the medical profession, of which he is a member, and gave him a seat in Parliament. If charges were brought against him, and vague suspicions alleged of the lamentable catastrophe of which he was declared guiltless; if the profession felt that they were getting mischief from his connection with them, would you, when the facts of the case had become obscured by them, think it unfair or unjust in that profession to say to him, "Explain to a jury of honourable medical men, whom we will choose, the circumstances which are said to be against you?" And if a public journal published a letter forcibly pointing out the evils arising from the connection, *bon gré malgré*, forced on them, would you think it right to acquiesce in the learned counsel's demand of giving heavy damages for such a letter? I am sure you would not. You would say that, to all these who are ill-fated enough to excite suspicion, there is but one pathway out of it—*investigation*; and that the right which enables us to call to account the suspected guilty, entitles us to call to account the suspected innocent. The embryo of doubt should not be left by a public man to lurk in the bosom of society; but if it be, and it assume a voice, as it needs must, it is a foolish dream to fancy that it can be destroyed by an action of damages, in which, as the learned counsel himself admits, the liberty to justify is practically denied us.

Mr. JERVIS—As this assertion has been made two or three times, I must remark that I made no such admission.

Mr. HEALEY thought that he had heard the admission very distinctly made, but of course, after that denial, must have been in error.

LORD CHIEF BARON—If it could not be justified, Mr. Healey, it could not be denied.

Mr. HEALEY—True, my Lord; but, in any case, this letter is so peculiarly circumstanced, is so vague and indefinite, and touches on such a variety of facts, that, on our side, no justification could have been framed which could not have been demurred to in law. And let me now say, Gentlemen, that of all men, and especially of all public men, the very last person should have been the plaintiff to have come into a public court, demanding damages for a letter of that kind; I say it with confidence, there never was a man who made a freer use of the liberty of the press, or——

Mr. JERVIS—I must object to this, unless evidence be produced.

Mr. HEALEY—The learned gentleman himself has delared that the plaintiff is the editor of the *Lancet*, and the law reports give us half-a-dozen cases in which his client stands a recorded libeller.

Mr. JERVIS again objected; and his Lordship, having decided that the law reports could not be noticed, except given in evidence as to certain facts,

Mr. HEALEY resumed—Though the plaintiff be at least a public journalist, I with force affirm that, while there never was another Member of Parliament or public character of whom such a letter as that could be written, there never was a public character or Member of Parliament but himself who, if such a letter had been written of him, would have gone into a court of justice to make a money action of it. We all recollect how, some time since, the journals handled Mr. O'Connell and Mr. Whittle Harvey on some alleged suspicions or charges. When these gentlemen found themselves, in the journals, the subject of public commentary and accusation, did they go into a court of law to ask damages? No such thing. They went to the House of Commons, and asked for a court of honour—a committee of inquiry. Those gentlemen actually said to themselves what this letter had said to Mr. Wakley. They uttered to themselves what Mr. Wakley would punish as a crime when uttered to him. They said public charges are made against us; they are important to us; they are important to those connected with us; we must either purge our character before a committee of our peers—men who know us, and what is inquired about—or we must let it go to the winds of public opinion. And I need not tell you that a good character will stand bushels of hard writing. A man must live, and talk, and write himself down, nobody can do it for him. Unjust writing injures nobody but the unjust writer, for who, Gentlemen, are the readers? Who especially are the readers of such a journal as that before you? Do you think that the learned and scientific readers of such a journal as that—those readers who are said by the learned council to be so considerable in number—do you think that they want the sense to detect, or the honesty to punish, a public injustice? Have they not the same feelings as yourselves, the same love of social right and justice? The medical profession form a perpetual jury on such a trial—a jury even better acquainted with the facts than yourselves—with the best possible power of punishing wrong, and no way slack, let the plaintiff be their witness, to exercise it. It is your privilege to watch tenderly over that right of free discussion involved in this trial, for, had we spiritless juries, careless of the virtue of our public men, and punishing with severity comments which, however unkind to the individual, are most kind to the public good, we should deserve that all our government, down to its very aldermanships and mayoralty, should be monopolised by low and characterless persons. Why should not you, the juries of England, secure to your public press, dealing with public characters, that liberty of discussion which the law gives its lawyers and the senate its members? The due administration of law requires that counsel should be licensed in every *bona fide* criticism on character brought publicly before them in evidence, and the public business of the country demands, for its full performance, that the censures of one public man on another, no matter how severe, should be shielded from the intrusion of law. The same reasons exist, and in stronger force, to guarantee the press in fearlessly exercising a most necessary privilege. Nor can I refrain from expressing my surprise that, in reference both to this freedom of discussion, and the intrinsic merits of his own case, the plaintiff did not confide the affair of this letter to that Court of Queen's Bench of which, as coroner, he is an officer, and which would have given him exemplary satisfaction, if he could only have shown it due cause. It was in his power, as it was indeed in his duty, to have applied there for a criminal information. That court is invested with a peculiar power for the protection of public characters from unjust aspersions, and, as a coroner and Member of Parliament, no man could be more secure of its protection, if he could demonstrate a reasonable claim. Gentlemen, it was not only his duty to prefer that becoming procedure, but it was his highest shield. If he had anything that distinctly resembled a respectable case, there is no lawyer in the kingdom who would not have advised him to this as the best and most becoming procedure. The experienced Mr. Chitty, in his "General Practice," expressly states that this is the proper course, where the plaintiff cannot, or will not, as in this case, negative the aspersions. [Mr. Healey here read the passage.] Why then did he not move the court for a criminal information? We have no explanation given; but this we know, that had he pursued this ordinary, this becoming course, he must have gone through a very useful, but not at all times very convenient preliminary. Turn to the 5th vol. of Bacon's Abridgment, and that learned authority will tell you that the court will not interfere where the matter complained of as a libel happens to be true, or where it was intended for reformation, not defamation. This, Gentlemen, was a very awkward circumstance. But there was another. The very first step the plaintiff would have to have taken would have been to have sworn on his oath that the facts and opinions announced in this letter were untrue. Such a course would have been the course of honour and of right English feeling, and is the customary course adopted by public characters when they think that they have been libelled. It gives the plaintiff the rare advantage, so priceless to a man who really has a character to sustain, of coming into court with clean hands at the first instant of his process, of forthwith purging himself of every suspicion, and of showing before the country that his object is not the low and mercenary aim of making money by a skilful use of the machinery of the law, but of really vindicating his good name. But, Gentlemen, there was also another course open to him. If the letter contained any such insinuations or charges, as the learned counse states, the plaintiff could have preferred a bill of indictment, and and the public would have had a justice done to them which this form of legal proceeding completely deprives them of. The plaintiff could have been examined on oath by you and me, on ever

matter there touched on. But in either of these cases he must have appeared in the witness-box himself, have stated on his oath whether the facts in that letter were true or false, and have undergone a searching cross-examination. Gentlemen, it does not appear to have suited the plaintiff to have ascended the witness-box; it does not appear to have suited him to have stated on his oath that the facts referred to were false; it appears not to have suited him to have undergone a searching cross-examination, and therefore he chooses the safer course of coming down here under the protection of this peculiar form of procedure to ask you to execute a labour for his character he has not executed for himself, and put a price on a thing which he has carefully shrouded in darkness. But, Gentlemen, I have too long occupied your time about this very paltry case, and now, bringing it to a conclusion, would briefly remark that myself and my co-defendant stand before you in this case as persons maintaining for themselves that perfect integrity of character they claim to have shown in those who, like the plaintiff in this case, assume to represent them. Nay, I go further, and say, that though we have been attacked neither unfrequently nor unseverely by the plaintiff, we have never admitted anything into the *Medical Times* which we did not believe to be in the performance of a duty to the profession. There are some duties that must be performed with more rudeness than others; and it is not at all times that we can so far consult the gentleness of our natures as to achieve a necessary right with "bated breath and whispering humbleness." The duty of defending ourselves and principles is at times urgent, and bears no nice balancing of terms. You must feel that we have not been fairly dealt with in this proceeding; you must see that the law has been used not for the purpose of clearing the plaintiff's character, but injuring us; that exactly that form of procedure which is unsatisfactory on the point of character, and most oppressive to us in point of operation, has been adopted; that if the plaintiff sought by his wealth to use the potent machinery of the law in the most efficacious way possible for our ruin, he would have acted precisely as he has done: and that, therefore, the malice in this matter is not in the libel, but in the action. We have exercised but a public duty in a public journal, to a public man, for a public profession; and had Mr. Wakley come forward, as he should have done, as a public man contesting our right, we should have had an opportunity of justifying what we have done, on the ground of public utility—the ground on which it actually was done. That was the only issue that should have been before you, and that is the very issue which the plaintiff has carefully excluded; but you will teach Mr. Wakley that the honourable, the just, the fair, the non-oppressive course of procedure, which would have left nothing in the dark, and shown no vindictiveness, is the only course which he ought to have taken, and that you will not support him in taking any other. You will not lend yourselves to be the agents of a mercenary vindictiveness, which has done everything to show that it has no one title to any favour at your hands or the hands of justice. Despite, then, the array of technical ingenuity so lavishly displayed, I am quite confident that, taking the whole case into your consideration, you will feel that you have fully discharged your duty, and done nothing inconsistent with the justice and good feeling that should grace your decisions, in giving the plaintiff what his own technical form of proceeding has secured him, and no more—one farthing damages.

The LORD CHIEF BARON, in a luminous charge, now addressed the jury. He said, that in most cases of libel, he would advise a party aspersed, to proceed in the other manners referred to by Mr. Healey; but in such a case as the present, where imputations were rather hinted at than asserted, and put so vaguely and indefinitely, that a plaintiff must first find out and shape the charges before he could deny them, he felt that Mr. Wakley had not taken the improper form of proceeding. The ground occupied by Mr. Healey, in reference to the duty of public journalists, was, he thought, untenable. No rumours about a public man should be noticed in a public journal, unless they could be proved to be true; that is a principle of law; and it was competent for the defendants to have justified even a part of the libel, if, from the vagueness of the rest, they were unable to justify the whole. Criticisms on public men should be guarded, and whether this letter, through personal malice—which did not appear to him the motive—or through mere vanity—which was more probable—went beyond the limit that should be set to public discussion—it was for the jury to decide. To him it appeared that it attacked Mr. Wakley as a *man*, more than as a public character. By the Act respecting libel, passed in August, 1842, a defendant might, in mitigation of damages, offer an apology before the commencement of the action, or as soon after as he had an opportunity. He might plead that it was inserted without malice, and that at the earliest opportunity an apology was inserted, or that it was published from gross neglect. Again, the defendant might plead the truth of the libel, or he might pay a sum of money into court, which the plaintiff might accept or not, and forego or persevere in the action, as he pleased. None of these courses had been pursued by the defendants, who had suffered judgment to go by default. If this letter were not a libel, it would be difficult to say what a libel was. The learned counsel has called the letter "stupid." In that opinion, he must say, he did not concur. He thought it displayed a considerable share of a very peculiar talent; and was the production of one who had a sort of power of writing severe things. (The learned judge went through the severe parts of the letter *seriatim* to the jury, remarking, when he came to the names of the gentlemen fixed on to form the tribunal, "Men, certainly, that stand very high in their profession.") The plain meaning of the letter was, that Mr. Wakley was a man of low and infamous character; he damages everything that is connected with him; let there be an inquiry: and such was the peculiarity of the letter, that this simple matter extended through three columns of the work. It was his duty to call on the jury, in their estimate of the letter, to consider the station of the plaintiff, the grave nature of the charges made against him, and to give such substantial damages as would compensate the plaintiff for the injury such a letter must cause his character, and the wound it must inflict on his feelings. The plaintiff had very properly claimed a jury of gentlemen to adjudicate the damages, who moved in the same sphere of life as the plaintiff and defendants, and they would be the most competent to fix on the substantial damages which would suit the justice of the case. At the same time, it should be mentioned that the defendant, by the fair and temperate observations he had made, had done nothing to aggravate the damages; but they must award such damages as the circumstances of the case and the nature of the libel demanded. The damages ought to be fair and satisfactory, and of such a nature as to mark the just sense which they entertained of the value of character.

The jury having left the court for three hours, considering their verdict, returned it in favour of the plaintiff—Damages £150.

After the jury had given their verdict, several of them crowded round Mr. Healey, making him very gratifying assurances of kindness and good feeling. They assured him that the protracted struggle was whether the verdict should have been £100 or £200, and that finally they had compromised the matter, and thus gave Mr. Wakley the extra £50 appraised to his character. One of the jurymen assured Mr. Healey that he was a strong political supporter of Mr. Wakley, having voted for him at each past election.

(To the Editor of the Medical Times.)

SIR,—It is my intention in this article to give a general view of the *French system of national education*, and in a succeeding number of your periodical another of the *French system of medical education*.

This detail of the glorious system of national education in France, the source of national enlightenment, honour, and moral power, will show by contrast the very humiliating position which England holds, what we are without, and what we ought to have.

My second paper will also enable us distinctly to estimate the merits of the French medical education (similar to the national education in principle, and of which it is only a branch), and from it we shall be enabled to deduce how medical education should be conducted in England, the moral principles which should govern the medical profession, and the causes to which most of our evils are to be traced.

The following facts I have obtained from various sources, principally from intelligent gentlemen who have been educated in France.

In the last named country the *rich and the poor have an equal opportunity of receiving the best possible education.*

Napoleon took the education of the people into his own hands, not for the purpose of bestowing government patronage upon any that he desired especially and personally to favour, but, on the contrary, in order, by wholesome and righteous laws, to encourage merit, to develope the intellectual resources of the country, to ensure the advancement of the arts and sciences, and to secure to each individual, according to his moral and intellectual deserts, and in ratio to the claims he thereby had on society, honours, emoluments, and distinction. Moreover, in order that this social system should be developed for the good of mankind, he took care to cleanse literature of those pestilential agencies which so infect and demoralise and injure our social state in England (more particularly that of the medical section of the community), viz., personal intrigue and favouritism, family patronage, money influence, and political partizanship.

The UNIVERSITY OF FRANCE, now termed "LE ACADEMIE ROYALE DE PARIS," established at Paris, presides over the instruction of the rising generation. It is, I believe, merely a university of government, and from it emanates every rule, even the most minute, by which the education is conducted.

The constitution of this board of government consists of a grand master, a chancellor, treasurer, and council. Not only is the grand master elected by a system of concours, but all the members of the council obtain their offices by the same system of promotion, as the result of their talent only, and they are selected in this manner from amongst the heads of the sub-universities next to be mentioned.

The Royal Academy of Paris, or University of France, is assisted in its labours by several minor universities or *sub-universities*, called "ACADEMIES." These are situated in some of the principal towns, and to each of them is allotted a certain number of departments or counties, in order that each may efficiently assist the Royal Academy of Paris in governing the education in those departments to which it belongs.

The academies have the power of granting degrees of bachelor of arts, bachelor of letters, and doctor of letters, which latter is the highest.

In each of these departments, moreover, is one or more "COLLEGE ROYALE," which is the school where the system of education is more especially carried on. These colleges have respectively a *principal, sub-principal, and treasurer*; the former constitute the government of the college, the latter has to receive and pay all monies. The principal, moreover, has to transfer a list of all his pupils twice or thrice per year to the "Academie Royale," and to the same establishment a certain sum for each pupil, reserving the overplus (so much for each pupil), for the payment of himself and teachers.

The system of instruction is as follows:—There are in the college seven classes, each under a teacher, who is denominated a "*regent*" or "*professor*." These classes are so arranged as to form a regular ascending scale of instruction; beginning in the seventh class with the first rules of Latin grammar, and so proceeding upwards to the first class, who are engaged in translating the most difficult Latin and Greek authors, with compositions, elocution, &c., which latter branches are confined to the two most advanced classes of the seven.

They also study history and geography, *which are divided amongst the seven classes:* the Bible history is allotted to one class; that of the Christian religion to another; ancient history to another; modern to another, up to the present time; and the history of their own country specially to another. There is after this first class (besides the seven), another called "*the class of philosophy;*" in this they take into consideration the subjects of logic, ethics, metaphysics, and natural philosophy.

The usual time devoted to each class is one year, so that the pupils are not hurried from book to book, acquiring from each a mere something of learning; but they are thoroughly grounded in every subject, and the pupil rises in regular succession by his proficiency through all the classes. It is calculated that at least three-fourths of the French army have gone through this course of superior education—hence their superior conduct.

Mode of Instruction.—In each class the pupils attend two hours morning and evening. In the intervals between these hours of attendance, the pupils are employed at their respective homes in preparing exercises for their next meeting, as they are not allowed to do any thing of that sort at the college.

Thus the whole time of each pupil when at the school is devoted either to learning the instructions given to the rest, or to that which is addressed to himself in particular; for the classes being very numerous, averaging from fifty to eighty or ninety pupils in each, it cannot be expected that each individual can give to the professors the *whole* of the instruction or translation for that particular day; but as they are called upon *indiscriminately* to say their lessons, they are all obliged to attend, and follow on their book what is being translated or recapitulated by the pupil who happens to be called upon at the time, as they are all expecting to be summoned suddenly to follow in the thread of the lesson (whatever that may be) and they are liable to be punished (no corporeal punishment, that depraves the mind) if they cannot do so; thus any remark the master may make to any of them must equally instruct all. The whole of the day is thus properly divided, and what is an especial advantage, by the pupils being obliged to prepare their exercises in their own domestic habitations between the hours of instruction, the parents are able to form a precise judgment regarding the abilities, the application, and disposition of the youths.

An Inspector is sent yearly from each academy to the colleges in their respective districts, for the purpose of reporting the conduct and merits of the teachers and the proficiency of the pupils. For this purpose he devotes two hours (at one of the times of meeting) to each class, when he sits in the room during the time that the teacher is giving the usual regular routine of instruction. Once a year, also, the public * are promiscuously admitted to one of the regular class meetings as inspectors.

Corporeal punishment, as already hinted, is entirely excluded from the system; but the pupil, for neglecting any particular lessons, or for any other positive fault, is punished by having a portion of one of the Latin authors to copy for a task.

The pupils, however, are further spurred on to exertion and emulation by the following admirable system of bestowing—

LITERARY HONOURS AND PRIZES.†—The *written exercises* which the pupils have to prepare consist of portions of Latin and Greek, as the case may happen, to be translated into French, and *vice versa*, which are dictated to them by the teacher out of any source he may think fit, not, therefore, marked out to them in books of which they could obtain keys or translations.

One morning in each week is set apart for a competition among the pupils in these exercises (Latin and Greek), taken in rotation in alternate weeks—in the later years arithmetic and mathematics being added. In this case *the exercises are done at the School*, so as to ensure their being the unassisted work of the pupils. Each pupil gives in his paper to the professor, who, during the course of the week, examines them all, and so classes them according to their respective merits, each pupil also getting a number assigned to him, according to the goodness of his exercise, which he keeps till the result of the next weekly competition is known. The first upon the list each week obtains and keeps during the ensuing week a *silver cross*, which is a badge of honour in imitation of the "cross of the Legion of Honour."

A record is kept of each of those pupils who have held the first place during the year at each of these competitions; whoever has been first the oftenest, must of course have been most proficient in all the *branches* of his education taught *in that class*, and is rewarded in the manner I shall immediately explain.

There is, moreover, at the end of the year, a similar competition amongst the pupils in each class of every college, in *each of the branches of education*, for the purpose of granting prizes for every respective subject.

The six pupils whose exercises are considered, in this instance, the best, are rewarded as follows:—The two first get the first and second prizes, the four next receive each of them a branch of laurel.

The six pupils who have been oftenest the first during the year share similar rewards; the two first on the list obtain prizes distinguished by the term "*prizes of excellence;*" the four following are called "*accessits*"—i. e., he came near. These *prizes of excellence* show that the pupils obtaining them have been proficient in *all branches* of their education. Whereas the obtaining of the first-mentioned prizes for Greek, Latin, &c., merely shows proficiency *in any one of these branches*.

All the above referred-to *prizes consist of books;* on the inside of the cover of each there is pasted a printed paper, signed by "THE PRINCIPAL," and setting forth the name of the college and class, the name and native place of the pupil, and the subject for which the prize was awarded.

There can be no favouritism, as the pupils have their exercises examined not by the teachers of the college to which they belong, but by those from another college. The name of the pupil who has written an exercise is also concealed beneath a seal, which is not broken until the moment of the distribution of the prizes.

The manner in which the prizes are delivered is as follows:—A platform is erected in the college yard, tastefully ornamented, on which seats are placed for the civil authorities of the town and county, the church dignitaries, military commanders, and any other persons of distinction.

Those are the persons who deliver the prizes to the successful candidates, and as the latter receive the prize, a *crown of laurel* is placed upon their head, and a military band plays a tune among the acclamations of the assembled multitude.

The friends of the pupils receive express invitations for the occasion.

Previous to the distribution of the prizes a play is got up under the management of the "Principal," on the platform, and acted by the pupils, who go in regular dresses for the occasion; it is generally uncommonly well performed, and is intended to test the proficiency of the pupils in *elocution*—it proves a great stimulus.

In Paris there are five colleges—or perhaps, at the present time even more than that—in order to suit the large population; those pupils in these colleges who are considered the best in their respective classes are sent from each of the colleges to have a similar competition as above described (this being an extra competition, designated by the term *concours*, being a contest of talent between the different colleges in Paris), and prizes are awarded in a similar manner as those already alluded to, but the merit of obtaining prizes in this case is much greater, as this contention is among the *élite* of the different colleges.

It is perfectly optional to the parents of the pupils to withdraw them from the colleges whenever they please, or whenever they think their children have received such a sufficiency of education as is in accordance with their views in life. But if it is intended that they should belong to any of the learned professions, they must go through the whole course of instruction, more particularly during the two or three last years, preparatory to their presenting themselves for examination at one of the "*academies,*" for the purpose of taking out the degree of *bachelor of letters and arts, which they must possess before they are allowed to commence on the study of* DIVINITY, MEDICINE, *or* LAW. They must, when they present themselves for this examination of bachelorship, produce *certificates* of having been educated in one of the colleges, as no other schools are recognised. But if any parent or guardian should wish to bring up his son or ward in his own house, it will be allowed; and then, instead of the certificate from the college, the parent or guardian must certify that the pupil has been educated in the "paternal house," under the tuition of an accredited bachelor of letters, and that the course of study followed in the colleges has been closely attended to; in either case the *moral* character must be particularly certified.

The certificates must be on stamped paper (a stamp costs two pence-halfpenny), and are then authenticated by the signatures and seals of the civil authorities, which in all transactions, according to the French laws, is a substitute for our (abominable) affidavit system. In France a person is quite as guilty of a crime by signing a document which he knows to be false, as in our country he would be, provided he swore it to be true.

The *price of instruction* in these colleges is fifty-six francs (£2 6s. 8d.) yearly, for a system of instruction not at present surpassed in the world. This price, be it remembered too, although low, does not require any specific recommendation or presentation—a system so disgracefully developed and nationally recognised in England. The yearly fee in the Paris colleges (I do not know why) is, I believe, 105 (£4. 7s. 6d.); but the instruction is, in no way, superior.

One defect in this system of national instruction is, that they are not taught to read and write; but this preliminary education can be obtained at so cheap a rate from private teachers as to be available by every mechanic.

The Children of all the Poor, on being recommended through the clergy or civil authorities, may receive their education *gratis*, and in many instances those are most distinguished in their classes.

Out of the fees above specified, the teachers receive their salaries, which vary according to the classes over which they are placed; in general, they begin in the lower classes, and are promoted, according to their deserts, as vacancies occur. The principals and sub-principals, &c., are chosen from those teachers.

In the class in which a person (an Englishman who received several prizes) was educated, who communicated several of the above facts to me, were to be seen the Prince of Wagram and the son of the meanest mechanic, intellect was so equally appreciated in each.

The same rules regarding the above-mentioned education apply equally both to Frenchmen and foreigners; and when we mark the liberality of this system of literary policy, and compare it with that of our own, as now existing in our (so-called national) colleges and universities, what a humiliating and disgraceful contrast!

Lastly, let it be remembered that the man who established this system of national education, whose code of laws has never yet been surpassed in excellence, whose great moral object was to establish in the world an aristocracy of talent and industry, and who, in consequence of his own almost superhuman talent, was chosen as the representative of the country which had adopted him—that this individual was, by interested individuals, held up to society as a monster, because he defended the

* How absurd in England for any thing of this sort (whether instruction or examination), which concerns the public welfare, to be kept private, as though the public were a set of barbarians.

† All laws regulating society should be founded on this basis: make it to be a man's interest to do that which is right, and against his interest to do that which is wrong; instead of punishing crimes, prevent them by these means; for, after all, man is a self-interested individual. Self-interest, properly exercised, is *virtue* (it is by the just exercise of that we wish to attain Heaven itself); but improperly exercised it is *vice*.

principles which had thus elevated himself and his country, and defended the latter, in its day of peril, against its hereditarily crowned-headed foes

Your obedient servant,

G. D. Dermott.

Charlotte-street School of Medicine, Bloomsbury.

THE NATIONAL ASSOCIATION OF GENERAL PRACTITIONERS.

The Association resolved, at their last public meeting, to add to the committee a certain number of provincial practitioners, in order that, in the event of the charter being granted, a body of gentlemen from the provinces might be ready, from whom Government could select the twenty-four provincial general practitioners who are to sit on the council of the new college. Instructions were forwarded to the honorary local secretaries to call meetings to give effect to this resolution; and the following gentlemen have already been nominated by the practitioners of their neighbourhood to the honour of a seat on the committee:—

J. Hurst, Esq., Bedford; nominated by the Branch Association of Bedfordshire, through T. H. Barker, Esq., hon. local sec.

G. P. Amory, Esq., Exeter; nominated by the South Devon Branch Association, through Joseph Hopgood, Esq., hon. local sec.

R. H. Gwynne, Esq., Bridgenorth; nominated by the South Shropshire Branch Association, through J. H. Martin, Esq., hon. local sec.

G. Rogerson, Esq., Liverpool; nominated by the Liverpool Branch Association, through J. P. Harris, Esq., hon. local sec.

R. H. Sleight, Esq., Hull; nominated by the Hull Branch Association, through James Dossor, Esq., hon. local sec.

T. J. Ficklin, Esq., Cambridge; nominated by the Cambridge Branch Association, through W. Hoblyn, Esq., hon. local sec.

Brewster Seabrooke, Esq., Brighton; nominated by the Brighton Branch Association, through J. Cordy Burrows, Esq., hon. local sec.

R. Mather, Esq., Grantham; nominated by the Branch Association of Grantham, through J. W. Jeans, Esq., hon. local sec.

W. Coward, Esq., South Shields; nominated by the South Shields Branch Association, through James Barron, Esq., hon. local sec.

S. S. Cory, Esq., hon. local secretary, Bridport; nominated by the Bridport Branch Association.

John Glover Loy, Esq., M.D., Whitby; nominated by the Whitby Branch Association, through John Taylerson, Esq., hon. local sec.

George Rowe, Esq., Haverfordwest; nominated by the Pembrokeshire Branch Association, through J. D. Brown, Esq., hon. local sec.

John F. Quick, Esq., Tiverton; nominated by the Tiverton Branch Association, through J. J. Coward, Esq., hon. local sec.

W. F. D. Dickenson, Esq., Ulverstone; nominated by the Ulverstone Branch Association, through George Gibson, Esq., hon. local secretary.

W. G. Carr, Esq., of Gomersal; nominated by the Dewsbury Branch Association, through H. Hemingway, Esq., hon. local secretary.

F. A. B. Bonney, Esq., hon. local sec., Brentford; nominated by the West Middlesex Branch Association.

R. T. Hunt, Esq., Salford; nominated by the Salford Branch Association through Thomas F. Brownbill, Esq., hon. local sec.

G. T. Scale, Esq., Landport, Portsmouth; nominated by the Branch Association of Portsmouth, through W. H. Garrington, Esq.

J. Dulvey, Esq., Brompton, Kent; nominated by the Branch Association of Chatham.

J. Sutton, Esq., Greenwich; nominated by the Branch Association of Greenwich and Blackheath, through F. K. Hunt, Esq.

C. M. Burnett, Esq., hon. local sec., Alton; nominated by the members of the Association in the Northern Division of Hants.

T. J. Rayner, Esq., hon. local sec., Birstal; nominated by the Birstal District Association, West Riding, Yorkshire.

J. W. Roberts, Esq., Bradford; nominated by the Bradford Branch Association, through R. Caton, Esq., hon. local secretary.

T. Paget, Esq., Leicester; nominated by the Branch Association of Leicester, through H. Harding, Esq., hon. local secretary.

George Chapman, Esq., Windsor; nominated by the Windsor Branch Association, through H. M. Champness, Esq., hon. local secretary.

R. Lowe, Esq., Bristol; nominated by the Bristol Branch Association, through J. Colthurst, hon. local secretary.

R. S. Leggatt, Esq., Eastry; nominated by the Sandwich Branch Association, through H. Pettman, Esq., hon. local secretary.

W. Allison, Esq., hon. local secretary; nominated by the Branch Association of East Retford.

J. M. Bryan, Esq., Northampton; nominated by the Northampton Branch Association, through H. Terry, jun., Esq., hon. local secretary.

C. H. Higgins, Esq., Taunton; nominated by the West Somerset Branch Association, through W. C. Pyne, Esq., hon. local secretary.

T. Thompson, Esq., Nottingham; nominated by the Nottingham Branch Association, through G. E. Stanger, Esq., hon. local secretary.

The committee make the following judicious remarks on the question of the practicability of country members acting on the Council:—

"The committee beg to inform the members of the Association and those gentlemen who are nominated upon the committee in particular, that in the urgency of the business of the committee from its first formation, it has been totally impossible to approach the subject of by-laws, but that the affairs of the New College will have to be conducted under a well-considered code of laws, and that some such an arrangement as the following will have to be adopted:—

That while every member, provincial and metropolitan, would, as a matter of course, be at liberty to attend every meeting of the Council, and take part in its proceedings, the business of the Council be arranged under three heads. 1. Ordinary business, which it would be competent for the metropolitan members of the Council to transact—as the settlement of current accounts, &c. 2. Questions which are to be submitted by voting papers to all the members of the Council, including the provincial members—as elections, &c. 3. Extraordinary business, which can only be transacted at a general meeting of the Council, to be held once, or at most twice, a-year, or at an extraordinary meeting duly convened for a special purpose. Under this last head would be arranged the curriculum of education, &c.

Memorials numerously signed, to Sir James Graham, in favour of the amended bill, have been sent to that gentleman through the Association from Luton, Woburn, Essex, Middlesex, Devonshire, Dorsetshire, Portsmouth, Windsor, Chatham, Yorkshire, Brighton, Norwich, Middlesex (western division), &c.

The following is the petition from the committee, now ready for presentation:—

To the Honourable the Commons of the United Kingdom of Great Britain and Ireland in Parliament assembled.

The humble petition of the Committee of the National Association of General Practitioners in Medicine, Surgery and Midwifery, in behalf of the Association, numbering upwards of 4,000 Medical Practitioners.

Showeth,

That your petitioners are firmly of opinion that the bill for regulating the profession of physic and surgery as amended by a committee of your honourable house, is eminently calculated to raise the character, and increase the usefulness of the medical profession, without injustice to any party whatever.

That your petitioners would apprehend very injurious consequences from the continuance of the existing agitation on the subject of medical reform.

Your petitioners, therefore, entreat your honourable house to give its sanction to the Physic and Surgery Bill in its amended form, with the view of its being passed into a law in the present session of Parliament.

And your petitioners will ever pray.

A MEMORIAL

ADDRESSED TO THE RT. HON. SIR JAMES GRAHAM, BART., M.P., HER MAJESTY'S PRINCIPAL SECRETARY OF STATE FOR THE HOME DEPARTMENT, BY THE ROYAL COLLEGE OF PHYSICIANS OF LONDON, JUNE 13, 1845.

The Royal College of Physicians of London feels itself called upon respectfully to address Sir James Graham on the important alterations which have been made by the Committee of the House of Commons in the bill for regulating the profession of physic and surgery.

Enactments, equally new and important, have now been introduced into it for the first time, which were never contemplated in the course of the discussions that have hitherto taken place between the College and Sir James Graham.

In order to explain its views respecting these enactments, the College begs, in the first place, briefly to recall to Sir James Graham's recollection the tenor of those discussions, and the circumstances connected with them.

Before any measures affecting the medical profession had been submitted to Parliament by the Secretary of State, the College had carefully investigated the grievances complained of in numerous petitions to Parliament for medical reform, and had laid before the Government some suggestions concerning them.

The most prominent of the alleged grievances were found to be as follow:—

1. The want of a general registration of licensed practitioners.

2. The want of some body or board to which questions of medical polity and of public health might be referred.

3. The existence of local jurisdictions, and consequent restrictions upon practice and inequality of privileges.

4. The want of uniformity in the education and examinations conducted by different institutions, and great disparity thence arising in the qualifications of practitioners passing under the same denomination.

5. The continuance of self-election into the governing bodies of the different medical corporations.

The College has already taken occasion to express to Sir James Graham its approbation of the manner in which the two first-mentioned wants are supplied by the bill, viz., by the system of general registration therein directed, and the establishment of a council of health.

With respect to the two following grievances, the College suggested that, provided uniformity of qualifications could be obtained, reciprocity of privileges might properly be granted. And it professed itself ready to concede to a considerable extent its own peculiar privileges, and to confer, without further examination, the license to practise in London, on the graduates and licentiates of Ireland and Scotland, *provided it could be assured that such licentiates and graduates had been educated up to the standard which the College had fixed as necessary for physicians.*

For the College has constantly retained, and often expressed its desire that nothing should be done to lower the standard of the general and professional acquirements of physicians: and it is but justice to Sir James Graham to state that he has always manifested a cordial participation in this desire of the College.

Nevertheless, the College fears that clauses which have been introduced into the bill are not unlikely to cause that standard to be lowered. For instance, the 23rd clause allows any university to confer the degree of licentiate in the faculty of medicine upon students, of the age of twenty-two, after five years of professional study, only two of which will have been passed in a university, and without any security for a preliminary education or examination in literature and science. Now, there will be no restriction to prevent these licentiates from graduating as doctors of medicine, so soon as they shall have reached the age of twenty-six, and that without further university residence or professional study; for the 22nd clause, the only one imposing any restriction on medical degrees, does not require for doctors of medicine

a term of residence of longer duration or a course of study of greater extent and comprehensiveness than those already specified.

This early age of graduation and limited course of study are clearly at variance with the intentions of the College and the spirit of the 16th clause of the bill, by which physicians ought to be devoted to their studies up to the age of twenty-six.

For the reasons which have been assigned, the College considers the 23rd clause to be inexpedient. It would seem also to be introduced unnecessarily, because by the 14th clause provision is, as it should be, made to enable those who wish to act as general practitioners to do so at an early age. And such persons may afterwards, by one of the provisions of the 16th clause, become physicians, if, by successful cultivation of medical science, they have raised themselves in general estimation.

With respect to the last of the grievances above-mentioned—self-election into the governing bodies of the medical corporations—the College offered to redress this grievance, as far, at least, as physicians of this country are concerned, in the most complete manner, by opening the fellowship to all licentiates of four years' standing, and by giving to all the right of voting in the election of fellows; as well as by other provisions of a liberal nature; especially, by offering to admit as associates, without examination and upon a reduced fee, all bona fide physicians now practising in England and Wales.

The College was then informed, by a letter which its president had the honour to receive from Sir James Graham in Feb., 1842, that if the alterations above stated, and others of a similar nature suggested in that letter, were made in the internal constitution of the College, it was the intention of Her Majesty's Government to propose a measure to Parliament whereby the powers and privileges of the College, as an *examining* body, would be greatly increased. According to the advice thus tendered, and with the sanction and co-operation of the law officers of the crown, the College proceeded to prepare, with considerable pains and expense, the draft of a new charter, embracing the alterations which it had itself proposed, as well as those suggested by Sir James Graham. The College has ever since been waiting for an act of the legislature to enable it to accept this charter. It deeply regrets that, meanwhile, the general bill, in conjunction with which the new charter was to have been accepted, has, in many respects, been materially altered.

As the bill was originally framed, the College was required, indeed, to surrender the examination of all Scotch and Irish physicians; but it was authorised to superintend the examination of all persons, of whatever grade, who should seek to obtain in this country a licence to practise medicine. And as the College was instituted for the promotion of medical science, it does indeed seem proper that to it should be entrusted the duty of testing the qualifications of all those who are to have the sanction intended to be given by the bill of being qualified to practise medicine, just as to the College of Surgeons was to be entrusted the duty of testing the qualifications of persons to practise surgery. In the bill, as previously framed, and even in its amended form, this idea is carried out in regard to general practitioners in Scotland and Ireland; for to the respective Colleges of Physicians and Surgeons, in each of those parts of the the United Kingdom, is entrusted the function of examining general practitioners. And the College believes that such a principle, if carried out in England, would ultimately give satisfaction to the great body of general practitioners throughout England and Wales, as well as tend to the advantage of the public.

By the amended bill, however, the authority to examine general practitioners is no longer given to the College of Physicians of England, although it is still given to those of Scotland and Ireland. Nor, in the opinion of the College, is anything like an equivalent for it afforded by the 17th clause of the bill, as amended, which clause prescribes only a *preliminary* examination before a joint medical and surgical board.

It does not appear to the College to be at all a proper arrangement, that persons, who have undergone a previous examination by physicians and surgeons, should be examined, subsequently, in medicine and surgery, by general practitioners.

It is a further and a greater objection to such double examination, that it must operate as a discouragement to medical education in England, since in Scotland and Ireland a single examination will be sufficient to qualify for practice.

With respect to the new incorporation, made known in the amended bill by the name of "the Royal College of General Practitioners *in Medicine*, Surgery, and Midwifery, of England," the College, without objecting to the incorporation of the general practitioners, would press upon the attention of Sir James Graham that, as the College of Physicians was specially founded for the promotion of medical science, and for the regulation of medical practice, there are strong objections to the assumption by this new institution of the title of the "Royal College of Practitioners in Medicine."

Nor is it to the assumption of a title only that the College sees reason to object. It must object, even more strongly, to the latter part of the 32nd clause, which gives to general practitioners the right to fill ALL *medical and surgical offices*, and thus confides the highest duties of the profession to the members of that class which is required to pass through the least extended education, and which is admitted to practise at the earliest age.

In offering the foregoing observations, the College is so fully convinced of Sir James Graham's desire to maintain a high standard of education for physicians, as well as to support the College in the discharge of its proper functions, and even to extend, if possible, its sphere of utility, that it cannot doubt that the remarks which a sense of duty has dictated, will be received with the candour and the attention which the College has met with from Sir James Graham on every occasion.

There are other points in the bill, of minor importance, to which the College is also desirous of requesting Sir James Graham's attention.

With respect to the constitution of the Council of Health, if the representative principle is to be retained, at least in part, there ought not to be two members of it returned by the College of General Practitioners, since one member only is to be returned by each of the Colleges of Physicians and Surgeons.

In clause 27, "For securing efficiency of examination," Sir James Graham has yielded to the wish of the College, that none but professional persons should be allowed to be present at the examinations. The alteration, however, which has been made in the composition of the Council, seems to render it even more desirable than before, in order to obviate some possible jealousies and interferences between the different orders of the profession, that no one should have an absolute right to be present at the examinations, unless deputed by the Council for that purpose.

As regards the arrangements for general registration, the College observes, with satisfaction, that the register is now expressly ordered to be received as evidence in courts of law. It does not seem, however, sufficiently clear whether the supplementary register, provided by the amended bill, is intended to contain the names of *all* persons now legally practising, as well those with general as those with only local privileges. Those also who are entered on the supplemental register, should be required to send in annually their names and places of abode, as ordered by a previous clause with respect to the register.

In some points the bill has been amended to the satisfaction of the College. In particular, the College approves of physicians and surgeons being compelled to enrol themselves in the college of the country in which they practise, under the penalty of being struck off the register; also of a penalty for false pretences of qualification being imposed by clause 38, not only on persons unregistered, but on those also who should use a name or title belonging to a class in the registry to which they do not belong.

In conclusion, the College ventures to express a hope that Sir James Graham may find it possible to modify the bill in accordance with the views which have now been respectfully offered, for thus, in the judgment of the College, it is likely to be productive of greater advantage to the profession and the public than can justly be expected from it under its present form.

FRANCIS HAWKINS, *Registrar.*

LAW INTELLIGENCE.

COURT OF QUEEN'S BENCH, IRELAND.

Thursday, June 17.

(SITTINGS AT NISI PRIUS AFTER TERM.)

(Before the Lord Chief Justice and a common jury.)

LIBEL.

Michael Larkin v. *Charles Gavan Duffy, proprietor of the Nation newspaper,*

This was an action for libel. The declaration contained four counts; the first setting forth the libel, and the others varying the charge and tendency in point of technical form. Damages were laid at £500. The defendent pleaded the general issue, and also the plea of justification.

Mr. Hatchell, Q.C., stated the plaintiff's case. The complaint was that the defendant, Mr. Charles Gavan Duffy, had published a libel upon him in his character as a professional medical gentleman, charging him in substance with being a quack. In the *Nation* of the 22nd of Feb. last, under the head "Answers to Correspondents," the following notice appeared:—"Our readers probably know so much of the mechanical arrangements of a newspaper as to be aware that one side of it is printed before the other goes to press, and that errors are in this way frequently corrected in the same number that contains them. In the first side of our present number we observe with great regret that a quack advertisement from Surgeon Larkin has crept in, which would have been excluded, if it had met the editor's eye before the first side was printed off." That paragraph had reference to the following advertisement, both appearing in the *Nation* of Saturday, Feb. 22:—

"STOMACH AND CHEST DISEASE.—Friends in town and country have represented to Surgeon Larkin that many recoveries from appalling stomach, liver, bowels, asthma, and consumptive diseases, published in the *Nation*, though on particular request, were not calculated to advance his interest. These considerations he now casts to the winds when opposing his duty to afflicted humanity. These generous impulses arise, no doubt, from their hopeless recoveries; and as a guide to others, these being strictly privileged, have been shown to gentlemen in the *Nation* office, to remove all doubt. On the earnest recommendation of philanthropic clergymen of all persuasions, his patients, he will in future send this valuable medicine to all parts, with ample directions, in packages (free) at 2s. 6d., on receipt of post-office order, or reference in town for payment. That all families, however healthy, may have one or more packages of this happy medicine, which will keep good for years, suited to infancy and the most delicate female constitutions, not only as a cure for existing diseases of the vital organs, but as an unfailing preventive that will arrest these colds, that neglected, produce bad coughs, inflammations, influenzas, asthma, and consumption. Over this latter scourge, in all stages this side of the actual gripe of death, it exercises an immediate healing control, inspiring hope that astounds both friends and patients; as also over asthma and burning anguish to stomach and other abdominal viscera. To the respectable non-medical public it appears a mystery that a modification of the same medicine can equally cure diseases of the chest as the abdomen; but with the faculty there is no difficulty, who know not only the intimate connection, but the sympathy that exists between these vital organs, especially in diseases. Mr. Larkin has been called to see many appalling cases of dropsy, even among the wealthy, proceeding from organic diseases of these all important organs improperly treated."

The learned counsel commented at great length on the alleged tendency of the paragraph in question

to injure the professional character of his client, and said that he would prove that it was not a "quack advertisement," and that it was not treated by the public as a fraud or an imposture.

Dr. George M. M'Cormick examined:—might have heard an affection characterised as "a boiling anguish of the abdominal viscera (laughter)?

Mr. Bernard Fullam (of the *Nation* office) proved that he had received advertisements from the plaintiff, whom he had heard called Dr. Larkin, the *Nation* makes an immense sacrifice with respect to quack advertisements; it loses a considerable revenue by their exclusion; Mr. Duffy's orders are, that he should never take an advertisement of an immoral or indecent tendency.

Several witnesses were next produced to prove benefits derived from Dr. Larkin's treatment, one of whom stated that in addition to the pills, he had prescribed for him as a regimen, "to drink milk, eat mutton chops, and take exercise."

The plaintiff's case then closed, and

Mr. O'Hagan for the defence observed, that the counsel for the plaintiff had alluded to the solution of Sir James Murray and the baths of Sir Arthur Clarke, but nothing more absolutely different could be imagined than the advertisements of those gentlemen and this of Surgeon Larkin. Sir Arthur Clarke's position is established, and the character of his baths is known, and the invention of Sir James Murray is recognised throughout the whole medical world as of the highest value. He is a physician of great ability and standing, and it is preposterous to introduce his name on such a trial as this. This action is without parallel. Of all the attacks which adventurous speculators have made in latter days upon the press, it is the most audacious and the most unjustifiable. It is not a political libel which is charged against the *Nation* —it is not an insult to the private feelings, or an outrage on the private honour of any man; it is the simple statement of a plain truth in plain language, compelled by his own unwarrantable conduct, for which Surgeon Larkin seeks to mulct Mr. Duffy in the small penalty of £500. The experiment is a bold one, and betrays no moderate confidence in the facility of the jury, and the credulous folly of the public. The complaint is so ludicrous, and the subject matter of it, the plaintiff's advertisement, so extremely absurd, that it is scarcely possible to come gravely to the argument. Mr. Duffy knew nothing of Surgeon Larkin—had no feeling of enmity towards him, nor any desire to injure him in the least. On the contrary, it was his clear interest not to drive from his paper an habitual advertiser; and if he had not had a motive better than that of hostility, and higher than that of gain, it is clear he would not have done so. There was no malice in his mind; and what was his conduct? Not that of a libeller, who achieves his object by dark allusions and unknown passages of the life of his fellow-man—by hints and insinuations against his reputation, which may mislead the community, and the truth of which they have no power to test. Side by side with the advertisement is the *Nation's* commentary: both are presented together to the public judgment; and if the allegation of the paper is a false one, its correction, in the plaintiff's own words, is put forward with itself—the antidote was given with the bane; and if the advertisement did not merit the epithet attached to it, all men had means of judging that that epithet was wrongful. To the honor of the *Nation*, it has been proved that a large sacrifice of revenue is annually made by the proprietor, because he systematically rejects advertisements injurious to public decency or the public health—in short, quack advertisements. A few of those of Surgeon Larkin had found their way into the journal without his knowledge, but at last, when in that which was the subject of observation in the alleged libel, "the gentlemen of the *Nation*" were vouched to sustain the averments of the plaintiff, his attention was called to the fact, and he instantly felt bound to repudiate the unjustifiable reference, and prevent the delusion which was attempted on the country. It was his bounden duty to repudiate the statement of Surgeon Larkin, and he did so in mild and moderate terms. At best, the guards against injury from unskilful practitioners are not sufficient. Persons have diplomas and degrees who are ill qualified to deal with the diseases of the people. The legislature is labouring to rectify the mischiefs of the system as it exists; but when men pass from the beaten track, and throw off even the restraints of that imperfect system, and propound nostrums the nature of which is unknown, and their character far more than doubtful, what journalist could allow his influence to be used for their diffusion without an utter disregard of duty, character, and honor? So Mr. Duffy felt, and, therefore, in simple words, he stated the mere truth. The advertisement of Surgeon Larkin is called "a quack advertisement." That is the alleged libel. Mr. O'Hagan then commented on, and explained the meaning of the word "quack," according to the lexicographers, and showed its apparent application to the advertisement, and observed that it seemed to him to be the very model of a quack advertisement. It professes to announce a discovery which the wisdom of four thousand years had failed to accomplish; and the great inventor uses language betraying an ignorance of the common rudiments of letters, for which a ten-years schoolboy would be whipped. It has the true old quack quality of perfect disinterestedness. Surgeon Larkin makes a painful sacrifice of his feelings "when opposing his duty to afflicted humanity." No care has he for pelf—no desire to profit by his "invaluable"—his "happy" medicine. He is impelled, by the purest charity, to press it, not merely upon the sick, but upon all the world, "however healthy," and, if he can accomplish his great design, the entire human race—man, woman, and child—will be blessed by living on his pills. The wretched half-crowns he despises, and only accepts as a sort of *honorarium*—a tribute of gratitude from his admiring patients to the benignant consoler of "afflicted humanity" (laughter.) His advertisement "quacks of universal cures"—asthma, liver, bowel, stomach, consumptive diseases—all yield to its magic power. Till now, these complaints needed several remedies, and the remedy of one would have been aggravation in the others. But Surgeon Larkin has mastered nature—harmonising her most violent contrarieties, and making easy that which her "prentice hand" had left impossible—and then, not only is his medicine universal in its action, but it is also immediate. Consumption—the scourge, indeed, of our country—which has swept so many of its brightest and its best from its desolated homes—which all the influences of climate and medicine, the profoundest science, the largest experience, the tenderest and most devoted cares, have been utterly unable to arrest in its blighting course, striking down family after family, and generation after generation with the silent certainty of fate—that awful disease, in any stage "this side of the actual gripe of death," is to be immediately controlled by Surgeon Larkin. But it is too much. The subject is not to be sported with. There is something too disgusting in this monstrous attempt upon public credulity to permit the dealing with it even in serious sarcasm. Plain, unmistakable, confessed, the quacking of this advertisement is written on its front, and it is impossible to conceive, that the simple reading of it should not abundantly demonstrate its character to every reasonable understanding.

Dr. Kane examined some of the pills purchased by the plaintiff—the result was, that he could not detect in either of them anything capable of exercising medicinal action, and he believed the mass of which they was composed was merely crumb of bread. He could not, however, swear to the positive absence of active medicine of a peculiar class; he would not swear to the absence of minute quantities of *digitalis*, for that is one of a class of very active medicines not capable of being recognised when in small quantities; in fact, the chemical test for discovering their presence would wholly destroy their existence; bread or flour is very commonly used for mixing these medicines.

Sir Henry Marsh, Bart., designated it as the very *beau ideal* of a quack advertisement; he never read one more perfectly so.

Dr. Corrigan was next examined—He expressed his disbelief of the statement put forward in the plaintiff's advertisement, and also an opinion that that document decidedly came under the denomination of "quack advertisements."

Mr. Robert Gunn examined—Is one of the proprietors of the *General Advertiser*. There are a class of advertisements known as "quack advertisements," which they wholly reject. Mr. Larkin brought an advertisement similar in terms to the one read here to day, and he rejected it as a quack advertisement.

Mr. William Hamill, sub-editor of the *Nation*, proved that he drew Mr. Duffy's attention to the advertisement, and that gentleman immediately thereupon wrote the paragraph complained of.

The Lord Chief Justice in the charge to the jury, defined a libel, according to law, to be a publication without justification or lawful excuse calculated to injure the reputation of another, by exposing him to hatred, contempt, or ridicule, and told the jury, that if they thought the paragraph complained of, to be of that nature, they should find for the plaintiff, not exceeding £500, at which the damages were laid.

The Jury, after a deliberation of about fifteen minutes, returned to Court with a verdict for plaintiff, 40s. damages, and costs.—*The Nation*.

Surgical Cases.—Under this title, Dr. Duncan has narrated, in the *Northern Journal of Medicine*, a series of cases occurring in his practice, at the Royal Infirmary, Edinburgh. The first is a case of suppuration of the knee-joint from injury. The patient, a female, had been kicked out of bed a month previous to admission by her husband in consequence of some domestic squabble, and fell on the left knee with great violence. Considerable swelling and inflammation followed, and when she came under Dr. Duncan's care, the knee was much swollen, very tense, and exceedingly painful—the slightest motion giving rise to great suffering. The integuments around the articulation, but particularly on the inner side, were much inflamed and tender. The articulation was evidently distended with fluid, the patella floated, and fluctuation was perfectly distinct. There was considerable constitutional disturbance. The skin was hot; pulse 120; weak. Tongue moist, reddish, with brown fur on centre; loss of appetite; and much emaciation. On the night after her admission, an opening formed spontaneously on the inner side of the knee-joint, and a large quantity of pus, mixed apparently with synovial fluid, was discharged, with some slight relief to the pain. As the opening was insufficient to give free exit to the discharge, the cavity still retaining a considerable degree of tension, a free incision was made into it, and a considerable quantity of matter evacuated. Opiates were given freely, ℥vi. of wine allowed daily, and the joint enveloped in an emollient poultice. These means were followed by a considerable improvement in all the symptoms; and on the 25th it is st ted that the pain was much less acute, and that the pulse did not exceed 80. The discharge, which consisted of purulent matter mixed with synovial fluid, continued in moderate quantity, and its flow was increased by pressure applied over the opposite side of the articulation to that on which the opening had been made. The patient after this went on exceedingly well, the cure being interrupted only by attacks of bilious vomiting and diarrhœa. The M'Intyre splint had been applied immediately after her admission, with the view of keeping the part perfectly at rest, and Dr. Duncan was anxious to keep it applied, because, from a great degree of lateral mobility which existed, indicating destruction of the ligaments, it was apprehended that partial dislocation of the articular surface would take place. The woman, however, would not allow it to be applied, and the consequence was the tibia became partially dislocated backwards. With the exception, however, of the deformity which this necessarily produced, it did not appear to interfere very materially with the progress of the cure, or the strength of the limb afterwards. One or two small abscesses which formed at intervals in the vicinity of the opening were evacuated, and some minute spiculæ of bone were discharged along with the pus, these being apparently from the internal condyle, the articulation itself having

been previously completely obliterated. She was discharged with the joint completely anchylosed, and walking easily with the aid of a stick. In another case of suppuration, occurring in a man, fifty years of age, from injury, the knee having previously been the seat of some chronic affection of the synovial membrane, the suppuration was very great, and extended high up the thigh, and down the leg. The pus was evacuated by incision, but the symptoms became aggravated, and the man died in ten days. On dissection, the cartilages were found detached from the bone, softened as if macerated, and eroded in many points; and there was extensive purulent infiltration as high up as the trochanter minor, and down to the middle of the leg. Dr. Duncan refers the difference of result in these two cases to the difference in constitution, the difference in the state of the articulation at the time the patients met with the accidents; and lastly, the difference of period at which the pus was evacuated. The woman in whom the case terminated successfully was in possession of a tolerably sound constitution, which had not been injured by her mode of life. In the man, on the other hand, it was the reverse, and although not absolutely intemperate, still he was in the habit of partaking pretty freely of ardent spirits. In the woman, the injury leading to the inflammation was inflicted upon a joint previously in a perfectly sound condition; whereas, in the man, there had existed apparently some chronic affection of the synovial membrane, a state of matters which not only militates against the parts taking on a healthy action, but likewise increases the liability of the other tissues entering into the composition of the joint to become affected. The principal cause, however, of the unfortunate result, was, the period at which the incision was had recourse to. In the woman, the pus was evacuated by free incision at an early period, whereas, in the man, it was not evacuated until the matter had made its way out of the joint, and had diffused itself pretty extensively amongst the muscles and tendons up the thigh and down the leg. Experience has clearly proved that the earlier incision is had recourse to in cases of suppuration of a joint depending upon inflammation of the synovial membrane the better. By delaying there is not only the risk of having the matter escaping from the joint, and burrowing extensively amongst the soft parts in the neighbourhood, but there is great danger likewise of the other tissues, the cartilages, and bones becoming affected, both of which occurred in this case, and led to the fatal termination. Much has been said about the bland nature of pus; but there is no doubt that when it is pent up it quickly erodes the articulating surfaces. The sooner, then, after suppuration is established that the matter is evacuated the better. The incision must be so made, and so large, as to allow of its free exit, and prevent it from lodging. For this purpose counter-openings may be required; and if at any time it should appear to bag at any part, free incisions should at once be made. If there be a doubt as to whether the collection is purulent or otherwise—a doubt which can seldom exist—it may be prudent, as suggested by Sir B. Brodie, before incising, to make a puncture with the exploring needle. These means, however, will be of little avail in very many cases, unless at the same time complete immobility of the joint be maintained. The state of the bowels requires, of course, to be carefully attended to, and the strength to be supported by appropriate means. Suppuration of the knee-joint is always a very formidable affection; but when it depends upon inflammation of the synovial membrane alone, uncomplicated with disease of the bone, the patient will recover, in the majority of cases, under properly conducted treatment preserving the limb, with, however, except in very rare instances, an anchylosed joint. The next case recorded by Dr. Duncan is one of extensive lacerated and penetrating wound of the knee, in a young man, twenty-five years of age, the injury caused by falling upon and breaking an earthenware basou. When admitted there was an extensive lacerated wound of about six inches in length, passing right across the anterior aspect of the joint, immediately below the patella. The ligamentum patellæ was completely divided, and a small fragment of the patella itself had been detached. The capsular ligament was likewise extensively divided, the internal condyle being completely exposed, and the external to a very limited extent. A consultation was held between Dr. Duncan, Sir G. Ballingall, and Mr. Syme, and it was decided that the circumstances of the case did not warrant immediate amputation. One or two small portions of partially detached fibrous tissue, and the small fragment of the patella which had been separated, were removed, and two small vessels which bled, were ligatured. The integuments were brought together by several points of interrupted suture, a straight splint extending from the middle of the thigh to the middle of the leg, was applied on the posterior part of the limb, and the whole extremity was laid on an extended M'Intyre splint. Cloths, wetted with water, were ordered to be applied assiduously, and a draught containing sol. m. morph. gtts. xl. was given at bedtime. There was some hæmorrhage during the night, and fever afterwards set in. Local inflammation was controlled by the free and repeated application of leeches. Union took place by the first intention only partially, but the man had not a bad symptom, and made a good recovery. The last case is one of dislocation of the patella, with extensive opening into the knee-joint by sloughing. The patient was a woman, thirty-five years of age, who had dislocated the patella a few months previously to the second accident, the last injury being accompanied by severe contusion of the soft parts, on the inner side of the knee joint and lower part of the thigh. She reduced the dislocation herself; but it was followed by considerable inflammation, and the formation of an abscess, which gave way at two or three points three days before her admission, and a considerable quantity of pus mixed with blood was discharged. On her admission there was still considerable swelling on the inner side of the knee-joint. The integuments were of a dark red colour, and the cellular tissue could be seen in a sloughing state through the different openings. The articulation itself was free from pain, and could be moved without giving rise to much uneasiness. There was no constitutional disturbance, but the woman complained of much weakness. The slough separated in about a week's time, leaving an opening of three inches in length into the articulation. The parts from which the slough had been detached, presented a healthy granulating aspect, and the surrounding swelling and redness had much diminished. The articular surface of the patella and the internal condyle were completely exposed, and presented a perfectly healthy appearance, not the slightest trace of irritation or inflammation being present. There was now some slight constitutional disturbance. The skin was somewhat hot. Pulse 100. Tongue furred, moist. A splint was placed behind the limb. The water dressing was applied, and an opiate antimonial was given every four hours. The constitutional disturbance continued for a few days, during which time leeches were repeatedly applied, but the pulse never rose above 110; and on the fifth day afterwards, when the state of the articular surfaces was examined by gently raising the upper flap of integuments, they were found covered with healthy granulations. The discharge was by no means very profuse, and consisted of an admixture of pus with synovial fluid. The red was now substituted for the water dressing, and a bridle of skin which existed between the large opening and a small ulcerated one below it was divided. During the progress of the cure, the wound began to contract, and continued to do so with considerable rapidity; the discharge at one time appearing to bag somewhat on the outer side of the articulation, a counter opening was in consequence made, so as to facilitate its escape. From the destruction of the ligaments there was a considerable tendency to a falling of the knee inwards, but this was remedied by the employment of lateral splints so applied as not to interfere with the dressing of the wounds. Two months after admission the opening on the inner side of the articulation had completely closed, but a small one still remained on the outer side, from which a few drops of pus were discharged. It was then evident that partial anchylosis had taken place, and the tendency to inversion of the knee had almost ceased, but it was thought well still to support the parts, and lateral splints of thick pasteboard, retained by means of the starch bandage, were accordingly applied. With the exception of the constitutional disturbance which followed the exposure of the joint, and continued for several days, and one or two attacks of bilious diarrhœa which yielded under the appropriate remedies, no symptoms calculated to give any alarm occurred during the progress of the case. When dismissed she could move about easily with the aid of a crutch, but was seen repeatedly afterwards moving about pretty easily, with no other support than a walking-stick; with which she has since dispensed.] Some months after her dismissal she returned to the hospital with an abscess on the inner side of the articulation, connected with a small portion of the articulation on the outer side of the patella, where the cavity had not been completely obliterated. This had been produced by some indiscretion on the part of the patient, who had been leading a very intemperate life for some time previously, in fact, she was in a state of intoxication when admitted, and had walked to the hospital without much inconvenience. The abscess was opened, and under the appropriate treatment got rapidly well.

At a meeting of the Royal Society, a paper by Mr. Sharp was read, entitled 'On the Ashes of Wheat.' The experiments recorded were undertaken principally with the ultimate view of ascertaining with exactness what quantity of inorganic matter is removed from the soil by the seeds of a crop of wheat. The author first inquires what is the average amount of the inorganic, or incombustible portion of wheat, a question to which no satisfactory answer has yet been given. The result of his experiment is, that wheat yields by slow combustion a residue of from one and a half to one and three-quarters per cent. He then proceeds to determine by experiment the degree in which this result is influenced by previous drying at different temperatures, varying from 230° to 260° Fah. and finds that a heat of 245° is not sufficient to expel all the moisture contained in wheat ... while the loss of weight is then about 8 per cent.; by a heat of 260° the amount of this loss is 10 per cent. When the heat is so great as to occasion decomposition, the saline matter contained in the wheat fuses, and a portion of the carbon becomes so entangled, or firmly adherent to it, as to be incapable of separation by burning. Hence he recommends, in order to obtain greater uniformity in the results, that the wheat subjected to these experiments should be dried at a low temperature, such as that of a room in summer, and be allowed to remain a few days under its influence. The author tried the effect of the addition of nitric acid, with a view to save time, by accelerating the combustion, but found that the results could not be relied upon when this plan was adopted, and he was therefore obliged to relinquish it. He next directed his enquiries to the ascertaining whether the quantity of inorganic matter was in proportion to the specific gravity of the grain, that is, to its weight per bushel, and this he found in general to be the case. The conclusion he deduces from this investigation is, that the mean amount of inorganic matter removed from the soil by the grain of a crop of wheat, is exactly one pound per acre.

THE TESTES.—Mr. G. Gulliver has confirmed Wagner's observation, that the general enlargement of the testicles which takes place as the period of procreation approaches, is accompanied by enlargement of the individual seminal tubes. During winter he finds that the seminal tubes of birds are tolerably thick and strong, but at the season of procreation semens accumulate in them, and their coats are so distended and attenuated that they are very easily ruptured. The same thinning and enlargement of the tubercles occur in the development of the human testicles at puberty.

CLINICAL LECTURES ON MEDICINE,

Delivered at the Meath Hospital,

By Robt. J. Graves, M.D., M.R.I.A., &c.

Let me now direct your attention to the case of Margaret Lauder, who was admitted a few days ago, for suppression of the catamenia, with obstinate vomiting and persistent gastrodynia. This woman, who is of slender make and rather delicate constitution, has been complaining, more or less, for the last four years, during the greater part of which she has been subject to pain in the stomach, nausea, and vomiting. About five months ago, a new feature was added to her disease; the catamenia became suppressed, and have not appeared since. The attack of vomiting comes on every third or fourth day, sometimes oftener, and is preceded by pain in the region of the stomach, darting across the epigastrium and towards the left shoulder. The fluid ejected from the stomach, which is extremely sour, and as she states, "sets her teeth on edge," is of various colours; green, yellow, grey, or whitish, but never black. There is no remarkable epigastric tenderness, and she finds that during a paroxysm, the violence of the pain is diminished by pressure.

The first question that suggests itself with respect to the nature of this case is, does this long-continued, obstinate, frequently-recurring pain of the stomach, nausea, and vomiting, depend on organic disease, or is it the result of mere functional derangement? This is a most important question, and one which you will frequently have occasion to put to yourselves in practice. You will be often consulted in such cases; your examinations will be watched by the patients and their friends with close and painful attention, and your decision awaited with all the intense anxiety of minds haunted by the idea of scirrhus. You cannot, gentlemen, be too deeply impressed with the importance attached to such decisions, nor can you apply yourselves too assiduously to the difficult task of making a distinction between organic disease and functional disorder. I am sure I do not exaggerate when I say, that as many professional reputations have been wrecked upon this point, as upon any other connected with the whole range of medical science.

With respect to the present case, my impression is, that there is no organic affection of the stomach. My reasons for coming to this conclusion are these. In the first place, the disease has lasted with more or less violence, for the last four years, and that without any remarkable increase. The cause which operated in giving rise to the gastric symptoms three or four years ago, and before the suspicion of organic disease could be entertained, is still in operation, or, in other words, there does not seem to be any recent modification of her ailment, any new change to destroy the identity between her past and present condition. In the next place, the very duration of the complaint is opposed to the idea of its being organic. Had it been organic, it would, in all probability, have terminated fatally before now; or, at least, it would have furnished unequivocal proofs of its existence. Scirrhus of the stomach seldom lasts for four years without exhi[illegible] of its true nature. Again, the matter from her stomach was never tinged with blood, nor has it ever been of a black colour, or consisting of a substance resembling coffee grounds. Now, I need not tell you, that where organic disease of the stomach produces erosion of its mucous coat, and actual loss of substance, there will be an oozing of blood from the eroded surface, and that the blood will be either thrown up unchanged and of its natural colour, or it may remain in the stomach until the fluids of that organ have acted on it, and then it will appear, when ejected, of a dark colour and broken down so as to resemble coffee grounds. In the next place, there is no remarkable epigastric tenderness, and during the paroxysms, the pain, instead of being increased, is diminished by pressure.

Lastly, the extreme acidity of the fluid ejected from the stomach, is more an indication of functional disorder than of organic disease. I do not lay much stress upon this point, but where a person who has been long subject to pain, nausea, and vomiting, throws up a fluid of an extremely acid taste, the disease is, *in the majority of cases, functional*. How are we to explain this? The acidity of fluid ejected from the stomach, in any considerable quantity depends on derangement of the secreting surface of that organ. As long as the secretion of the stomach is carried on in the natural way, it never becomes a source of annoyance; a certain quantity of acid gastric juice is poured out at certain periods in the day, and these periods correspond in the normal state with the times of taking food, or in other words, this acid juice is only poured out when it is necessary. But in states of deranged action, where the secretion is altered by functional disorder, the stomach pours out this acid juice in excessive quantity. You will find a patient affected in this way vomiting a fluid, which if it fell on powdered chalk or soda, would produce a brisk effervescence, in consequence of the large proportion of acetic and lactic acid it contains. I have seen cases in which there was absolute corrosion of the teeth from frequent eructation of this extremely acid secretion.

It is clear, that the formation of acid in the stomach is merely the result of an alteration in its secreting powers, and not in consequence of any acetous fermentation of the ingesta. Now, this being the case, if the stomach be extensively diseased from organization, the consequence of scirrhous or cancerous ulceration, its secretions will be still further altered, and very frequently in such cases the products of secretion will not be so acid as they are in cases of functional disorder. Organic disease deranges the function of the stomach so much, that the secretion of acid is more or less interrupted, and hence we do not find the fluid ejected so sour as it is in functional derangement. I, therefore, look upon the extreme acidity of the fluid thrown up by this woman as connected with functional disturbance rather than actual disorganization.

I am aware that this opinion is somewhat different from that advanced by Dr. Osborne in the twenty-first number of the *Dublin Journal of Medicine*; Dr. Osborne seems to be of opinion that scirrhus and often cancer of the stomach are the results of functional disorder: there is nothing of which I am more convinced than that they are essentially different. I have known many persons afflicted for years, nay, for life, with the most aggravated form of *acid dyspepsia*, in whom no tendency to organic disease ever displayed itself. That the slow process to which is owing the gradual formation of scirrhus of the stomach will often occasion *acid indigestion*, long before the scirrhus is formed or has reached any degree of maturity, no one will deny. Dr. Osborne has been anticipated in almost all the propositions he has advanced, by Dr. Prus, of Paris, in a book published several years ago, where the same means of averting scirrhus are recommended. I fear that neither Dr. Prus nor Dr. Osborne have as yet discovered this important secret. They certainly deserve our best thanks for the attention they have bestowed on the subject.

Acidity of the stomach is frequently, but not always accompanied by gastrodynia or pain in the organ. In our patient, violent pain precedes the attacks of vomiting, and is occasionally present during the intervals. There is, however, no connection between pain and acidity of the stomach, for you frequently have severe gastrodynia in cases where the matter ejected has not the slightest acid taste. This is the case in pyrosis, where the fluid thrown up is quite limpid and tasteless. Here it is very probable that the fluid consists chiefly of the secretion of the pancreas.

In enquiring into the symptoms of which dyspeptic patients complain, you will find some *with weak stomachs and strong bowels*, while others have *strong stomachs and weak bowels*. The former complain of acidity, flatulence, distention and uneasiness of the stomach after meals, and have a capricious or indifferent appetite. They suffer much from eating certain articles, and are consequently obliged to be careful in the selection of their food. The digestion thus imperfectly performed in such cases by the stomach, is effected with more energy by the remaining portion of the intestinal canal, and hence the fæcal mass is quite healthy, and contains no unused alimentary matter. In order to enable the bowels to perform more efficiently the supplemental digestion, so necessary where the principal agent, the stomach, has left so much undone, the alimentary mass is detained longer than natural in the intestinal tube. In such persons, costiveness or a slow action of the bowels, is essential for the more complete solution and absorption of the nutritive portion of food which the stomach had, as it were, neglected. If by means of medicine or diet you promote a quick action of the bowels, and a speedy defecation in such persons, you impair the supplemental digestion, and injure, rather than serve your patients. In cases of this description we frequently observe that although great disturbance of the stomach ensues after meals, yet there is little or no emaciation or loss of strength; the sufferers are often of a robust, phlegmatic habit. The function the digestion which attributed to the stomach for the office of chymification, a step necessarily supposed to more advanced process of chilification, theory will take place in the small intestine, and in the above not explain the phenomena according to this theory, cases, for nutrition must, according to the degree in be impaired exactly in pr[illegible]

which the stomachic digestion fails. Here, the theory of digestion which rests upon the authority of Tiedemann and Gmelin comes opportunely to our aid. According to their experiments it appears that the nutritive efficiency of digestion depends on the solution and subsequent absorption of the soluble and nourishing portions of the alimentary mass. *Now, solution and absorption are performed by the whole extent of the alimentary canal*, but most energetically by the stomach and the cœcum or commencement of the large gut, which two parts are the chief secretors of the acid solvents. From this it follows, that when the stomach fails to perform the whole of its duty, its deficiencies may be supplied by the intestines. The history of intestinal fistulæ when the excrementitious matter is voided through an opening in the small intestines, proves that a man may live without the discharge of the functions which the large intestines are intended to perform on the alimentary mass. Again, those rarer cases of stomachic fistulæ which have been observed, almost suggest the possibility of life and nutrition being sustained, although imperfectly, without the aid of the stomach; for we cannot believe that this organ performs its functions with anything like natural energy, when it is placed in so unnatural a situation, and has suffered so much from previous disease and morbid alteration of structure. What is wanting in such cases to prove that nutrition may be carried on, nearly altogether independently of the stomach, is supplied by other organic diseases of that organ. Thus, in the case of *Napoleon Bonaparte*: the body was by no means wasted, on the contrary, there was a great accumulation of fat; "the fat was upwards of one inch thick over the sternum, and one inch and a half over the abdomen; upon opening the abdomen, the omentum was found remarkably fat, and on exposing the stomach, that viscus was found the seat of extensive disease; strong adhesions connected the whole superior surface, particularly about the pyloric extremity to the concave surface of the left lobe of the liver, and on separating these, an ulcer, which penetrated the coats of the stomach, was discovered one inch from the pylorus, sufficient to allow the passage of the little finger. *The internal surface of the stomach in nearly its whole extent* was a mass of cancerous disease, or scirrhous portions advancing to cancer; this was particularly noticed near the pylorus; the cardiac extremity, *for a small space near the termination of the œsophagus*, was the only part appearing in a healthy state."

Now, Gentlemen, in this and similar cases, it is evident that no part of the digestive function had been performed by the stomach, probably for several weeks, or even longer before death, and yet the body was so sufficiently nourished by the supplemental action of the small intestines, that we are almost tempted to believe that if by a miracle, the cancerous mass including the whole stomach had been removed, and had been replaced by a portion of duodenum, the individual might have lived for a time! But to return to our subject—where the stomach is strong, but the intestines weak, there is generally an excellent appetite, and the patient is a great eater—he never suffers from distention of stomach, uneasy feelings, acidity, flatulence or heart-burn after meals, however he may have indulged; he boasts, and justly that nothing ever disagrees with his stomach. He is nevertheless lean and ill-thriven; the reason is because his bowels do not possess the same energy with the stomach, and consequently do not perform their part of the business of digestion well; this is evident from the frequent and sudden attacks of looseness to which such persons are liable; their discharges are irregular, but on the whole the quantity of matter evacuated *per anum* is much greater than it ought to be; they seldom [illegible]ss solid healthy coloured stools—there is [illegible]dence of a hurried secretion of bile, and a too r[illegible] passage of the alimentary mass through the inte[illegible]. The fæces are therefore during their occasi[illegible] attacks of indigestion crude and semi-digested, [illegible] almost constantly fluid or semifluid; such pers[illegible] have two or three bilious, loose motions eve[illegible]y, and generally enjoy in other respects tolera[illegible]ood health.

Having pointed out these varieties of weak digestion, varieties which have scarcely been noticed by authors, but which nevertheless deserve especial attention, I shall conclude by observing that the distinction between organic disease and functional disorder of the stomach is often attended with extreme difficulty, and is to be drawn not from any one symptom, but from an attentive consideration of the history of the case, and the effects of remedies.

I have seen cases of indigestion, vomiting and extreme emaciation continue for month after month, until every medical attendant of the patient believed that death from organic disease was at hand, and yet the patient perfectly recovered; on the other hand I have seen the *stomach ailment* trifling when organic disease was extensive. I am anxious to impress this upon your minds lest you may be misled by any thing I have said in a previous part of the lecture, and lest you should think that I attach undue importance to any one symptom, *as for instance, the morbid secretion of acid by the stomach.* Dr. Osborne seems to look upon this rather as a symptom of commencing scirrhus; in this I cannot agree with him; probably we are both wrong; it probably cannot be relied on as characteristic either of functional disorder or of organic disease.

LECTURES ON THE PHYSIOLOGY AND DISEASES OF THE BRAIN,

By J. Bouillaud, D.M.P., M.A.M.,

Member of the Chamber of Deputies, Professor of Clinical Medicine at the University of Paris, Knight of the Legion of Honor, Physician to the Hospital de la Charite, &c. &c.

LECTURE III.

In order to complete the gener[illegible] review of the functions of the nervous centres, [illegible]ose of the cerebral lobes, the seat of the mora[illegible]nd intellectual faculties remain to be examined. These faculties are numerous, distinct from [illegible]h other, and act differently. Reasoning a[illegible] to a certain exten[illegible] experiments, prove this [illegible]rtion; besides which, the shape of the brai[illegible] and the great number of convolutions, furnis[illegible] anatomical arguments in favour of the op[illegible]n. Again, the brain is composed of two sub[illegible]es; the medullary substance in which the [illegible]rent movements arise, whilst the phenomen[illegible] sensation, the moral and intellectual facu[illegible] have their seat in the cortical substance; [illegible] is so true, that more or less intense acute [illegible]ammation of the latter is constantly accomp[illegible] by more or less delirium which is the forerun[illegible] mental aberration, if the phlegmasia become[illegible]ronic. Vivisections fully confirm these clinical [illegible]s, for on cauterizing or destroying the cortical s[illegible]ance superficially, the animals become mad or [illegible]ous, and rush desperately forwards without be[illegible] conscious of what they are doing, or where they [illegible] going. These are the results obtained in the nu[illegible]us experiments I have performed relative to th[illegible]ject on which, in my *Traite de l'Encephalite* [illegible]lished in 1825, I expressed myself as follo[illegible]—"If we reflect that intellectual disturbance[illegible]y exist independently of any other lesion of [illegible]erebral functions: and if we consider that th[illegible]tellectual disturbances seem to coincide con[illegible]y with disease of the cortical substance, we [illegible]onclude that disorders of the intellect are dep[illegible]t on distinct lesions of the cerebrum, whi[illegible]e seated in the cortical substance of that o[illegible]." The problem of the functions of the gr[illegible]stance seems to be more complicated, since [illegible]earches of Dr. Baillarger, who discovered six [illegible]ct layers in this substance, which he describ[illegible]arately, and to which he attributed peculia[illegible]omical characters. There remain the func[illegible] over which each of these layers presides, [illegible]o be indicated, but in all probability, som[illegible]e will elapse ere this important questio[illegible] be solved. But it may be asked—are ani[illegible]hen the brain is destroyed, deprived of the [illegible]llectual and moral faculties? Undoubtedly t[illegible]re: such as sight, hearing, taste, smell, [illegible] It is, however, certain that animals r[illegible] certain degree of tactile sensibility, since [illegible] paw be irritated, they withdraw it, and though this movement is performed as it were instinctively, still it shows that feeling is not entirely lost. It is, notwithstanding, highly probable that the brain has no power over the animal and actual perception of all the other sensations, but that it is destined to *intellectualize*, if such an expression be permitted, to preserve, to compare, and to recall them. The seat of the will is likewise evidently in the brain, for without the cerebral lobes the animal may stand erect, and perform certain automatic movements, but without any motive, end, will, or determination. Other faculties, such as music, certain dispositions for painting, drawing, writing, speaking, &c., all the different faculties and dispositions have their seat in the brain. But which are the organs, what are the parts which preside over each? These questions phrenologists have of late thought it possible to solve, though in truth, it is even now all doubt, schism, and controversy, and it must be confessed they are very difficult to answer. In short, every creature deprived of its cerebral lobes, is at the same time deprived of its intellectual faculties; all that remain are some slight instinctive qualities, which are evidenced by a certain number of automatic motions.

The opinion of Gall on the localization of the faculties and senses has been warmly combated, especially by Dr. Flourens, who states that when the brain is wounded in one of its parts, so that a sense is destroyed, all the others are likewise immediately abolished, and that the same result is obtained by a faculty or will. These conclusions are completely erroneous, inasmuch as they are too arbitrary and exaggerated; in fact, it is not correct that when one sense is lost, all the others are likewise annihilated. Thus, an animal after the removal of a greater portion of the cerebral lobes, does not appear to hear, to see, &c. and yet if the paw be pinched, it is withdrawn; if it be tormented, it cries out; if thrown into the air (if it is a pigeon) it is aware of the position in which it is placed, and of the danger it runs, and it stretches its wings so as to prevent its falling too suddenly, in a manner perfectly spontaneous. This act, instinctive or not, is not the less spontaneous, and indicates really an intellectual exertion of a peculiar nature; I will even say, it is almost an act of volition which produces it. The bird left at peace is stupid and motionless, seems to be deprived of will, no longer seeks its food, though it swallows when seeds are put into its beak, and appears to feel no kind of external irritation, yet from time to time it puts its head under its wing, as it did ere its cerebral lobes were destroyed. Now, is this movement instinctive, or is it the result of an act of the will, of a spontaneous determination of the bird? It must be confessed, that it is very like an act of the will succeeding to an internal sensation. Be this, however, as it may, one thing is certain, that it has its source in a faculty which persists after the more or less complete destruction of the cerebral lobes, a faculty which consequently lasts after the abolition of the greater part of the other faculties. If we admit with Dr. Flourens that sight and hearing have their seat in the brain, it may be asked if they occupy the same place as the intellectual faculties properly so called, by which we are enabled to recognise objects, judge their qualities, uses, and the relations they have with each other? Experiments prove sufficiently that this is not the case, since I have frequently removed different parts of the cerebral lobes without causing the least disturbance in sight or hearing, although several intellectual faculties were completely lost. The facts recorded in a memoir read before the Academy of Sciences many years ago, establishes this assertion beyond a doubt. But it may be asked how is it possible to hear and see when objects can no longer be appreciated? A physiologist will not be embarrassed to answer such a question, on reflecting that the child, for instance, *sees and hears*, long before he can appreciate the persons and objects *seen and heard.*

In a work published by Dr. Calmeil on the pathology of insanity, very interesting facts are mentioned, which come to the support of the doctrine I profess. "A woman affected with general paralysis, to such an extent that she was unable to

move off her chair, became incapable of distinguishing her left, from her right, hand; it was requisite to dress and undress her, put her to bed, and feed her; she *saw*, she *felt*, she *heard*, but she *had completely lost the faculty of thinking*; there was abolition of the intellect which took place gradually, and as it were insensibly."...... "A soldier from political events became insane, and immediately after the commencement of the disease he presented all the symptoms of general paralysis. At a later period, he was unable to *walk*, he soiled his linen, he *seemed to look with pleasure on the food placed before him, but he spoke not, his intellectual faculties were completely abolished.* The last thirty day of his existence it was necessary to push the food back as far as the fauces, as the instinct by which we seek to prolong life, was completely abolished." Is it possible not be convinced after perusing these facts?

According to the opinion of Dr. Flourens, all parts of the brain must act similarly, and one must alone replace the whole cerebral lobe; but I have shown that this is not the case. If by any means the anterior lobes are removed, the animal loses a certain number of its faculties, whilst, on the contrary it retains others. After such a mutilation, it moves about, continues to hear and see as usual, but it can no longer recognize surrounding objects; the dog no longer knows its master, nor the food by which its hunger can be appeased; it sees the objects but can no longer appreciate whether these objects may be useful or injurious. "The idea, the notion of food and its qualities, is, in a great measure, an idea added to the sensation which the object gives rise to, and this idea ceases to be perceived, or understood, as soon as the anterior lobes are removed, though the animal continues to see. Now the faculty of appreciation is entirely intellectual, and differs essentially from the sensorial faculties." The dog which was experimented on in this case, barks still, but it barks at every thing, as well at its master, as at strangers, and attacks every thing near it, animate or inanimate. I kept likewise several pigeons whose cerebral lobes were destroyed by cautery; these birds sometimes attacked with fury all that approached them, whilst at others they remained motionless with a stupid, idiotic look.

These animals (dogs for instance) move about automatically; they are however aware of the danger attendant on a fall, and have an idea of height, for if placed on a window sill, they walk to and fro, but take good care not to throw themselves over. They therefore see, and this sense is followed by an act of the intellect, by a species of judgment, and yet they are idiots with respect to the appreciation of the greater number of surrounding objects. Consequently if in removing the anterior lobes of the brain, certain faculties are destroyed, whilst others continue, it is evident that these lobes preside over functions different from those of other parts of the brain, and the opinion announced by Dr. Flourens cannot be considered to be correct, especially as it is in direct opposition to clinical facts. On the contrary what I stated as the result of my experiments is fully confirmed by *authentic* cases, few in number it is true, as facts of this kind are not numerous, and have but seldom been recorded. Those to which I here allude were published by Dr. Calmeil, and the patients whose cases are described, had fallen into a state of stupidity analogous to what I observed in animals whose anterior cerebral lobes had been destroyed; they presented more or less marked lesion of the cortical substance of these lobes, complicated by more or less considerable alterations of the meninges.

From the preceding facts it may be concluded, 1° That the cerebral lobes are not the seat of all the external senses, and that certain portions of these lobes may be removed or disorganized without these senses being necessarily lost.—2° That the senses and the intellectual faculties are perfectly distinct from each other, though both tend to the same end. 3° That the anterior or frontal portion of the brain is the seat of several intellectual faculties, and that its destruction produces a *state of idiocy*, of which the principal sign is the loss of the power of appreciating surrounding persons and objects, and which exists simultaneously with the external senses.

If now we proceed still further and examine the more special faculties such as speech, and memory of words, we shall find that the doctrine of Dr. Flourens is more and more erroneous. In fact, the abolition of the faculty of speech has always its origin in a serious lesion of the anterior lobes; it must, however, here be clearly understood that there exists no disorder of the organs of voice, or articulation, nor of the sensitive or motor nerves distributed to them. In the cases in which these organs are perfectly sound, the lesion must necessarily be sought for in the brain, and it will constantly be found in *some*—I do not (as Gall asserted) say any *particular*,—portion of the anterior lobes. But are these disturbances in the functions of speech always the same? They may be included under several principal types, which may, however, offer some modifications, and undergo various changes, which by their identical reproduction in different persons, and by their peculiar signs may be classed in categories. Now it often happens that the faculty of speech undergoes exclusively one of these typical disturbances, is abolished in one point of view, whilst all the other phenomena of this function, all the voluntary movements and the other senses remain in their normal condition. These facts* prove that Dr. Flourens was wrong, when he stated that if one faculty was destroyed all the others were destroyed also, but that there are cases in which a faculty may be partially, not completely, abolished. For instance, an individual whose muscular apparatus of voice and nerves of motion and sensation are in their normal condition, may lose the faculty of making use of them, and have no longer the power of putting them in action, although he recollects perfectly the words which are formed in his brain, and has merely forgotten the manner* of expressing them by the muscular apparatus of speech, for if a pen is put into his hand he writes his thoughts and his wishes, in short all his feelings perfectly well, whilst it is impossible for him to utter articulate sounds. There are other individuals who, correctly speaking, do not lose all power over the muscles of the larynx, since they can utter a certain number of words, but as the same words return constantly, they are quite unable to communicate their ideas to those around them. They are aware that they do not speak their thoughts, but it is in spite of their will that their vocal organs pronounce the same phrases, the same words or the same syllables; when they write, this no longer takes place, evidently indicating that the words corresponding to these ideas are still formed in their encephala. There are again other persons who are not only in the same state as far as speech is concerned, but likewise retain but the remembrance of the words they pronounce, so that if requested to write down their thoughts, they can only transcribe what they incessantly repeat. In these there exists evidently a double lesion, not only of the remembrance of words, but likewise of pronunciation, although the latter may be contested, as nothing proves that the patients were incapable of uttering other words had they been formed in their brains. Finally, others have lost completely the remembrance of words; if desired to write something, they are unable, being incapable of remembering a single word. But have they in these cases lost the power of employing the mechanical and physical organs of pronunciation? They perhaps have no more lost this faculty than that of moving their hands to write, but as they have lost the remembrance of words, the organs destined to pronounce them remain inactive, being no longer excited, the same remark being applicable to the hand with which the patient endeavours to write.

I will not prolong further the examination of the localization of these faculties, for it is evident, contrary to the opinion of Dr. Flourens, that they are perfectly distinct from each other, and that they may be localized in separate parts of the brain, easy of appreciation. I do not, however, mean that the problem which Gall thought to have soved in assigning precise and determinate localities, to the numerous faculties is true, since I consider it impossible that such should be the case. It may, however, at the present time be asserted almost affirmatively that the intellectual faculties depend on the anterior lobes of the brain, whilst the instinctive faculties are seated in the posterior. I admit therefore the basis on which Gall founded his doctrine of the localization to be correct, but I cannot admit the numerous divisions deduced therefrom, because in many instances facts have demonstrated that they are erroneous. It is to be hoped that a day will come in which clinical observations and experiments will enable us to obtain the results which this distinguished physiologist thought to have realized, and that the science of localization will take its place among positive and established facts.

In the succeeding lectures we shall examine meningitis, general paralysis, and ramollissement.*

*In a special article, the classification of the diseases of the brain as professed by the distinguished physician of La Charité, will be given at length.

REPORTS ON DISEASES OF FEMALES By EDWARD RIGBY, M.D.

Fellow of the Royal College of Physicians, Senior Physician to the General Lying-in Hospital, Lecturer on Midwifery at St. Bartholomew's Hospital, Examiner on Midwifery to the University of London, &c.

(Continued from page 218.)

This is a case of inflammation of the cervix uteri, coming on at a period of life when the catamenia are about to cease, probably depending upon some of the precursory changes connected with that time, and complicated with serious and obstinate derangement of the chylopoietic functions.

Its details are spread over a considerable period of time, and although they have been in some measure condensed, they nevertheless occupy much more space than I could have wished. They are, in fact, the details of a wearisome and long-protracted struggle between a strong disposition to establish organic disease in a system, the powers of which were threatening to break down under severe functional derangement, and the active and varied treatment which was required to withstand it.

Although she had been suffering from an inflamed state of the cervix uteri, and from lancinating pains of this part for some time, and although the os and cervix were generally found hard, swollen, and intensely painful to the touch, no alteration of structure appears to have taken place, from the fact, that occasionally, when relieved by leeches or by the catamenia, it would become soft and almost natural. This is a fact which I have pointed out in a former case, where, besides the pain and hardness, considerable alteration of form was evidently taking place, and where, nevertheless, it became soft and natural on the unexpected occurrence of pregnancy. I have already shown that lancinating pains, even when very severe, are not necessarily connected with organic disease, and the details of this very case are quite sufficient to make me confess my inability to determine how long they may exist, without being attended with change of structure.

As the catamenia were suppressed, slight inflammatory action of the left ovary showed itself, but was successfully counteracted by the antimonial ointment.

The treatment consisted chiefly in rousing the liver and bowels with brisk doses of calomel, and in diminishing the local congestion and excitement of the general circulation, by leeches to the os uteri and anus, by bleeding, and by saline laxatives; the action of it was occasionally still further promoted by the use of digitalis and nitre. I also ventured occasionally to improve the state of the stomach by a vegetable bitter with mineral acid.

On several occasions a considerable amendment was produced; but again and again the lancinating pains returned with great severity. As these symptoms increased, the os uteri was again carefully examined, and gave sufficient evidence to make me fear that change of structure had already taken place, when an unexpected relief (as stated by her) is said to have followed, by the discharge from the vagina of a considerable quantity of

purulent fluid, producing great alleviation to all her symptoms. I can only presume this to have been an accumulation of unhealthy secretion locked up in the cavity of the uterus, by the swollen state of its os and cervix, although the examination showed nothing as regards the size of the uterus which might have led me to suspect it; on the other hand, it is but fair to confess that the sensitiveness of the patient, and extreme tenderness of the os and cervix uteri when touched by the finger, might have caused me to examine the inferior segment of the uterus less carefully than I should otherwise have done. She continued to attend for two weeks after this occurrence, and feeling quite well, I saw no more of her.

The change in her symptoms, on resuming attendance at the hospital two years afterwards, was very remarkable: the expression of the face was quite altered by the staring prominence of the right eye, which still in great measure continues, although its vision and the various cerebral symptoms have so greatly improved. After a long and severe struggle, I have succeeded in overcoming the undue activity, or rather violence, of the circulation: the use of the lancet was seconded by antimonials and brisk purgatives, and as soon as the general symptoms had abated, the local congestion was brought under control by a seton in the back of the neck, under the effects of which she has made very decided progress.

The catamenia having ceased entirely for half a year, there will probably be but little chance of the former uterine symptoms returning, although time alone can prove whether the seeds of organic disease have been sown in these organs. The well-known cessation of vascularity, which gradually takes place in the female generative organs, after, what is called, the "change of life," leads me to hope, that if she passes five or six months without the appearance of any uterine disease, she will have a pretty good chance of enjoying health for many years to come.

LEUCORRHŒA.

In entering upon the subject of leucorrhœa, it will be found to be by no means an easy task to assign any precise or very definite character to this disease, for under the above head is commonly brought every species of uterine and vaginal discharge which is not exactly bloody or purely aqueous.

Although the name, strictly speaking, refers only to a white discharge, we have every shade of colour, from the milky white to the dirty brown; every degree of consistence, from that of water, to a thick purulent, ropy, or even semi-gelatinous condition: every variety of odour, from the almost inodorous secretion of simple leucorrhœa, to the fetid discharges in certain malignant diseases.

These discharges vary also in their source; some being furnished by the vagina, some by the os uteri and canal of the cervix, others by the membrane lining the cavity of the uterus. They may be mucous, muco-purulent, purulent, or aqueous; running at times more or less, even in the same case, into each of these forms. Many of them depend on certain morbid conditions of some portion of the uterus or vagina, and therefore cannot be looked upon as separate and peculiar diseases, but merely as the effects of morbid processes, some of which, viz., inflammation of the os and cervix uteri, I have already alluded to.

The connection between the condition of the assimilating functions and the secretions of the mucous membrane, is still but imperfectly known, and we have not yet sufficient data to enable us to associate certain characters of these secretions with certain conditions of the general health. It is by time and careful observation alone that we can hope to collect the necessary evidence for this purpose. The secretion in the present case is as clearly a deranged secretion as those, under certain circumstances, of the alimentary canal, the kidneys, skin, &c.; and as in these organs the abnormal state may either depend on local causes of irritation or derangement; or it may depend upon an unhealthy vitiated state of the circulating fluids which afford the necessary pabulum for secretion.

The *local* causes of leucorrhœa are necessarily numerous, and produce different forms of the discharge; their action is much more distinct and usually more simple, whereas those which arise from the condition of the general health, and from some peculiar diathesis of the system, do not always afford us such satisfactory data.

I propose to consider the subject of leucorrhœa under the following heads: the simple; the white creamy or albuminous; the acute, and the chronic. It is a division which I have used for many years in lecturing, and although perhaps open to objections in some respects, it is nevertheless one which will be found to answer sufficiently all practical purposes.

The simple leucorrhœa arises from a relaxed condition of the vagina, and is therefore observed in women in whom the tone and vigour of the general health have been more or less impaired. It is, in fact, nothing more than an increase of the natural secretion of the vagina; the vessels which furnish the discharge permitting a larger proportion than usual of the watery part of the blood to pass through their secreting orifices. This condition has been admirably described by Sir Charles M. Clarke, who pointed out the valuable fact that the corrugation of the mucous membrane lining the vagina is in an inverse ratio to the quantity of its secretion: that where, from the contracted state of the fibrous or proper tissue of this canal, the rugæ are numerous and well marked, the secretion is sparing; that where the vagina is flaccid and relaxed, the rugæ are few and imperfect, and the discharge profuse. In the former case, the contracted state of the fibrous tissue of the vagina compresses the vessels which pass through it to supply its mucous lining, and thus controls the quantity of blood which is conveyed to the mucous membrane for the purpose of secretion; the relaxed condition of the canal, in the other, permits a more than ordinary supply of materials to furnish the discharge. That the contracted state of the vagina and corrugation of its lining membrane, are in direct proportion to the health and vigour of the patient: that where she is suffering from debility and loss of that tone which is the characteristic of health, the rugæ diminish or disappear. Thus, we see that women who live in damp unhealthy situations, and are prevented from taking sufficient exercise in the open air for maintaining the necessary state of health, are peculiarly liable to this form of leucorrhœa. Among the young women of this metropolis who are compelled to earn a bare subsistence by many hours of sedentary employment in close ill-ventilated rooms, the health and strength become so impaired, that few of them are entirely free from the complaint. Women residing in low marshy districts are peculiarly liable to this affection, whereas those who live on high ground and enjoy the bracing air of the mountains, are seldom subject to it. From the same reason we see it extremely prevalent in hot climates, especially where the high temperature is combined with much moisture in the air, producing a very relaxing effect upon the system.

ON THE SUPPOSED ADVANTAGES OF A KNOWLEDGE OF ANATOMY TO THE ARTIST.

By Dr. Knox, F.R.S.E., F.R.C.S.E.,

Corresponding Member of the French Academy of Medicine, and Lecturer on Anatomy and Physiology, &c. &c.

There still exists a prejudice, for such we shall find it to be, that an artist ought to study anatomy. By anatomy is here meant the anatomy of the human frame. As this opinion has been supported, and still is by many able men, artists and others, it seems right that it ought to be carefully analysed; if found correct, let such studies form the future basis of the artist's education; if incorrect, let him abandon it at once and for ever; when the great names have withdrawn themselves from the field, we shall know how to deal with the twaddlers; a right value may also be then adjudged to a couple of lectureships on what is called Pictorial Anatomy, now existing in London and Edinburgh. In founding these institutions, the patrons must have themselves been convinced that a knowledge of anatomy was not necessary to the artist, seeing that they refused the lectureship to "anatomists;" but it is a pity if such lectureships really are, as I well know one at least to be, a mockery and an insult to common sense, that they should be sanctioned or patronised by any respectable person. But to return.

Convinced as I am by an extended inquiry into the theory of beauty, both as regards the antique statue and the present living model, that a knowledge of anatomy is neither essential nor useful to the artist; that a beautiful figure and an anatomical figure are the antithesis of each other; that beauty consists chiefly in a skilful concealment of the anatomical structure or internal machinery of the frame, I beg leave to call the attention of artists and men of taste generally to the following analysis of the works or writings rather of Da Vinci, Mr. Haydon, and Sir Charles Bell, as the three authors of most note and authority upholding the ancient prejudice; let the artist weigh well what is said in the following critique, assured that it is not a hasty analysis nor a sudden change of opinion, but one which I arrived at with great difficulty; all, or nearly all authority was against the opinion I here advocate; my own views I respectfully leave in the hands of the artist and of the man of taste.

Review of the Principal Writers on Pictorial Anatomy.

I.—Da Vinci.

Is a knowledge of anatomy necessary to the artist? to the painter and sculptor? Should that knowledge be profound or superficial? Is it essential to the artist, and to the execution of works of high art, or of low art? Such was the opinion of Da Vinci, of Michael Angelo, of Sir Joshua Reynolds, of Mr. Haydon, of Sir Charles Bell. But such was not the opinion of Mr. John Bell, a fact I did not know till but a few weeks ago; with his opinion, formed seemingly in Italy shortly before his decease, my own coincides, formed several years ago. I have always foolishly enough hesitated to avow it, over-awed by the authority of great names.

To explain how this deep conviction arose in my mind that a knowledge of anatomy is not essential to the artist; that it is even disadvantageous to him in some respects; that its display destroys "the beautiful;" that nature intended that what she had made visible, that alone she intended to be beautiful; that alone she decorated, bestowing on certain minds the instinctive powers of discovering "the beautiful" in nature; I shall examine very briefly the remarks of Da Vinci, Mr. Haydon, and Sir Charles Bell; smatterers about pictorial anatomy, I need not even allude to; they live by their trade and write for their living; hack composers, copyists, their opinions are below criticism.

Da Vinci must have been gifted with those extraordinary natural abilities, in the absence of which no man ever yet rose to great and surpassing excellence. The error lies in some supposing that these are sufficient in themselves, without study, without experience, without knowledge, without repeated exercise of the mind. The necessity for all this, in addition to genius, was perfectly well known to Da Vinci; that such was his opinion I gather from his work, respecting which I shall now beg to offer a few remarks.

In order to discover a child's natural ability, or rather as far as I can interpret a very obscure passage, his want of ability for painting, observe, says he, that such children "draw much and simple lines, but finish nothing with light and shade." This is, I think, the meaning of Chapter IV.

He points out very beautifully and simply that quality of vision by which we can perceive *correctly* and minutely, and as a painter should perceive, but one object at a time; this physiological fact he clearly understood. But above all, his directions how to heighten and correct the imagination, that is, "the recollection of objects seen," are astonishingly minute and oft repeated. He was evidently profoundly acquainted practi-

* Traité de la Peinture: Folio: Paris, French Translation. Drawings by Poussin.

cally with the most correct mode of acquiring ideas: from physical objects *through the sight*, this being the sense employed almost solely by the painter, and this being the sense to which the painter directs and addresses all his labour. He beautifully describes the result of much habit and exercise, as ending in an instinctive or mechanical and easy performance of that which was at first gone over with great difficulty. Thus, no faculty of the mind bearing on his own studies escaped him. He calls this instinctive execution of difficult works acquired by much labour, "Comme sans y penser; la Faculte des Practiciens."

He recommends a constant appeal to nature on the ground of defective memory; how just this is! others have arrived at the same truth who probably never read Da Vinci. "And I now see how superior painting from nature is above everything that our imagination, assisted by our memory, can conceive."—(Letter from David Wilkie to a Friend.) He divides the head into twelve parts, and each part into twelve seconds, and so on.

In infancy the breadth of the shoulders equals the length of the face, also the space from the shoulder to the elbow when the arm is bent, and that from the navel to the pubis, and from the knee to the foot. But when man attains his full height all these measurements are double, excepting the face: at this time his total height is ten faces, and the breadth of the shoulders two faces, and all the above measurements are two faces.

He knew the preponderance which the head has in children. The flattening and broadening out of the fingers and toes when bent had not escaped him. He refers to a treatise on anatomy composed by himself, which I have never seen.

The measure of the extended arm is not that of the flexed one by the difference of one-eighth of its length. The wrist narrows when the hand seizes an object, and broadens out when relaxed, but the fore arm does exactly the reverse; the first seems to me to depend on the position of the thumb during flexion. The knee alone of all the joints diminishes in flexion, and enlarges during extension. The engravings illustrating the text of Da Vinci are, in the preface to this work, said to be from sketches by the celebrated Poussin:—what the originals were cannot now be known. The engravings are coarse, and altogether incorrect as regards the skeleton of the arm and foot, but yet have an astonishing accuracy of mere outline, showing the hand of a master. I have remarked the same in those anatomical drawings of Da Vinci, engraved by Chamberlaine. I mean those of the skeleton: they have not the slightest pretension to accuracy of detail, but are perfectly inimitable in spirit of outline. I know not how to explain this, having never seen the originals.

The anatomical drawings of Da Vinci, as they are called, are said to have been purchased by Charles I, and so came into England; that they were in existence and in the possession of the Crown in the time of George III, appears certain, from the preface to Chamberlaine's two fasciculi of engravings of a few of these original drawings by Da Vinci. Now, these engravings do not in any shape give an idea of the anatomy of any part of the body, further than the mere outline; strictly then they cannot be called anatomical drawings. When in London a few years ago I endeavoured, but in vain, to get a sight of Da Vinci's original portfolio; all that I learned was, that they were locked up in Carlton House; this was during the regency, if I rightly remember, of George IV. It is said that they cost £12,000; being unquestionably public property, an enquiry ought to be set on foot to ascertain where they are.

The great secret in respect to the admirable power of the original great masters seems to have been, that they were constantly sketching the human figure at times when not observed, and thus caught up all the instinctive human actions: these are the only natural ones. They also discovered that in nature no one object exactly resembles another; hence that variety which they studied to the very utmost—they repeated nothing, if possible. The variety of nature's works is endless. I have seen three hundred head of red and white oxen, purchased from a dealer, and being driven successively and singly past a coloured man, a Hottentot; his fine and piercing sight caught up in an instant in what each individual differed from another; on their being made thus slowly and deliberately to pass before him on three or four different days, he could recognise and single out any one of these oxen from another herd of thousands similar, at the distance of a year or more.

Da Vinci gives a singular advice which it were well to note in more senses than one—it is this. Let an artist take the measurements of his own frame, and ascertain where there is any disproportion, and let him take especial care to note this for the purpose of avoiding drawing it. Now, Da Vinci asserts that artists are continually in the habit of representing themselves, and that they do this by an instinct. When I read the passage I at first supposed that they did so from copying by means of a mirror, but this evidently is not what he means: but the instinct spoken of can only be a profound knowledge of self, derived from long experience.

The cartilages of the nose differ in different persons in eight modes: he mentions these modes, but they are not important—his observations on the forehead, the grand feature in man's face, are trivial—ten sorts of noses are spoken of.

In respect to attitude he says, "*la fontanelle ou clavicule de la gorge*," ought to fall perpendicularly on the foot supporting the figure—changing its position, however, with every change in the position of the person: he gives odd names to the muscles, names peculiar, no doubt, to the early Italian era. But as I proceed with this work, composed prior to the reign of Francis the First, I find some very strange statements regarding the *anatomy of the human body*—the description, for example, of the "largest chord in the human body without muscles," which, according to this translation is placed in the arm! "four fingers breadth above the palm of the hand, binding the bones of the fore arm together." Had Da Vinci not then seen the interosseous ligament connecting the bones of the leg? or has his translator mistaken his meaning? He describes a sesamoid bone in the shoulder which assuredly does not exist, and he speaks of one "de la poitrine," which is a vague word, but still there is none there. Were we quite sure that Da Vinci knew really nothing of exact anatomy, which I most sincerely believe, it would go far to prove that anatomy is not necessary to the artist, and that he merely requires to draw what he sees, without knowing the meaning thereof. This great question I have already discussed. Da Vinci writes as if he had never examined the knee-joints; if the translation be correct there is no mistaking this; but on all that came within his immediate observation of the *living body*, and on the influence of the mind, using this phrase in its most comprehensive sense, his remarks seem to me perfect, and are admirable.

The use of the mirror to compare the drawing with nature he himself considers as the grand secret; he remarks with true Italian minuteness that an artist looking at the reflection of his own painting in a mirror, "seems to regard the work of another," and by a quality in the mind common to most persons, may discover more readily its faults. His remarks on light and shade, and on those painters who neglect shade for the sake of that glare which attracts the vulgar and ignorant, are severe but no doubt just.

In conclusion, it is my belief that Da Vinci knew nothing of the anatomy of the human frame, beyond an occasional glimpse of the skeleton or a few of the surface muscles; that the story of his dissecting for ten years is an old woman's story, devoid of all foundation in truth, and that if he really did dissect in this way, he merely discovered by such labour the fact, that the office of the painter is to draw what nature has made *visible*, and what she intended should be made *visible*. By his profound tact as an observer, and a skill of hand which nothing could exceed, he discovered that there were at least two modes of pleasing the eye in drawing; the first by a mere sketch, an outline or line, yet drawn so accurately and with such spirit as immediately to suggest to the mind the intention of the artist, that is, the nature of the object intended to be represented; the second mode, of which also he was a perfect master, was the giving to the drawing the most perfect finish the pictorial art admits of, by his representing all the minutiæ of the object drawn, so as to admit of the closest inspection. In this latter, both are combined—modern artists often dispense with both in drawing the human figure as placed in modern landscapes; trees and lawns, sky and forest, rocks and lakes, are first disposed neatly enough at times, when it is discovered that something human or some being might enliven the scene, and a perfectly shapeless thing is put in somewhere to fill up space, of which figure it may be said that if illustrative it was not by

"Shape nor feature"

Or a desolate ocean rock, on which reposes at last the hull of a noble vessel, shipwrecked, and in ruin—the sea may be tolerably well painted, and so also the rocks—rocks being of many shapes it would be hypercritical to complain of them; but this would not suffice for the Art Union; and so to startle and give effect, a rounded shapeless mass, clothed in red or blue is stuck on the top of the rock: this is to represent the shipwrecked mariner, desolate and forlorn—white paint and varnish completes the painting. I have known committees of "taste and virtu!" give a hundred pounds for things like the above, which in a year or two might be purchased at their intrinsic worth; three or four pounds sterling.

II.—Haydon.

Section I.—It is my intention to dedicate this present division to an examination of Mr. Haydon's latest work, entitled, "Lectures on Painting and Design." Mr. Haydon is not an ordinary person; he is, as is well known, a man of distinguished genius; his taste, (whatever may be his pictorial powers, and of these I am no judge), his taste is undeniably good and unquestioned. Let me proceed at once to analyze the principles contained in a work composed by him who first discovered the true value, the inestimable worth of the Elgin marbles. We may almost describe him as the discoverer of the Elgin marbles. Lord Elgin, it is true, first discovered them in Athens, but they were re-interred in Britain, in the mire of London ignorance—commercial, trading, jobbing, cliquing London. The Academies could not find them out—the public taste, alas! including the Court, preferred Vauxhall, and the Lord Mayor's show—his gilded coach—but, above all, the King's procession to Parliament, the predecessors of Tom Thumb, and Gog and Magog.

The work contains an engraving or lithograph of the human skeleton; a stilted figure, with more of the semblance of the ape than of the man; without grace or dignity—unworthy of Haydon, and indeed not drawn by him, but "by a pupil under his direction." Throughout the work, indeed, the lithographs are most wretched; and even admitting them to be the work of a pupil, Mr. Haydon might have kept in view the distinguished pupils he had himself taught: Etty, Landseer, Lawrence, and many other illustrious names. It argues well for the teacher that genius, such as these, came from his school.

But why not have given us some spirited sketches or etchings of his favourite Elgin marbles, instead of such vile things as are met with in these lectures. To soften this criticism it is but right to admit, and I do it without the least hesitation, that no draughtsman on earth, nor Phidias, nor Apelles, nor Da Vinci, nor Titian, ever can give the "skeleton" a look of beauty, grace, or dignity. The matter is too solemn, and when we hear people talk of a beautiful "skeleton," I think they must be foolish, or suppose others foolish. Nature, no doubt, made the skeleton, but she also clothed it in the most scrupulous manner; I repeat, the sight of a skeleton is revolting to a right mind—a mind possessing a true and correct taste; its contemplation is tolerated, and even much sought after for the profound scientific truths it unfolds—but to call it beautiful, pah! the soul revolts at the idea.

Now, if we look narrowly into this skeleton figure, drawn by Mr. Haydon's pupil, it is easy to see that, like those of Da Vinci, and indeed, of all painters, it is a mere outline; it scarcely seems to have belonged to an European. Where is the

spheno-parietal suture? It might however have been wanting in the head delineated. What a beautiful confusion there is about the collar-bones: still the outline is accurate like those of Da Vinci, and this would seem to be quite enough for the artist; the outline and nothing more—the same as in Da Vinci, already quoted. To call this a drawing of the human skeleton, such as we have in Albinus and Cheselden, and in many other great anatomical works, were a mere burlesque and a play on words. The second figure is a comical one—it is the skeleton of a lion set upon its hind legs in a human or biped position: and what makes this of the more consequence to be noticed is, that we are afterwards told by the illustrious artist himself, that it was from accidentally putting the skeleton of the lion into this position, that he made the grand discovery which led him to the principles of high art, and to the detection of that secret, which disclosed to him the real source of beauty in the Antique, but more especially in the Elgin marbles—the true objects of Mr. Haydon's adoration. But the setting the skeleton of a lion in this way, and pointing out how it differs from man, is perfectly ridiculous—nothing can be more absurd. He *selects* an animal with a long body and *short* legs—sets it up upon these legs, and then tells us how ridiculous he looks. But let the lion or tiger raise himself on the bars of his cage, or in the area of the circus upon these same legs, and then will be seen the difference. Why *set* *et* an animal with short legs? set up the horse in this position, will he want dignity so placed?—by no means. Therefore, is it singularly illogical in Mr. Haydon to draw from these two sketches the conclusions he has done, and to the consideration of which we shall arrive in due time as we follow the lectures.

Of Mr. Haydon's preface we shall not speak here; it offers up a lamentable picture of what may be done in the way of coterie and clique oppression. I may return to it in speaking of the condition of what is called Pictorial Anatomy in Britain, and more especially in our northern capital. Let us proceed to the substance of the lectures themselves.

There are seven lectures.

Mr. Haydon starts with a proposition that Genius cannot be acquired.* "Industry will improve mediocrity, but will never elevate mediocrity to power." By power is of course here meant *genius*; for as to elevation to real power why, mediocrity is your only chance; it secures your entrance into good society; a *fauteuil* at the council table of all Royal Societies and Academies. In Town Councils it secures the Mayoralty for its possessor—in universities it is the only sure passport to a chair. So much for the advantages of mediocrity; others it may have, but these it certainly possesses.

Mr. Haydon is wholly and entirely anatomical; he sets out with the following theories: "*Form* is the basis of all art, and a deep knowledge of the human form is the basis of the knowledge of the forms of all other objects in nature." This view cannot be supported. But he adds still farther, "a power of drawing the human figure as it ought to be drawn is the foundation of the power of imitating everything else a painter requires to use, as an instrument to convey thinking."

As the human figure resembles nothing else in this world, as it is altogether specific, its outline never can be made the basis of any other object whatever. What resemblance, for example, does it bear to trees? to temples? to the secluded valley? the great mountain? the savage lion? the expanded ocean? the summer cloud? the harvest field and waving crops? it is impossible even to fancy that it does; and, therefore, Mr. Haydon's meaning perhaps is this:—"the outline of the human figure is so extremely difficult to delineate well and naturally, that when once attained in perfection, the artist may then draw anything else." This is my exposition of Mr. Haydon's theories; these are not his expressions, but my own. Be it remembered also that the Greeks never dissected.

Section 2.—The origin of the fine arts is not an unimportant question; and, first, to determine what is "fine art:" do the frightful Chinese things belong to this category? the Indian gods? the hideous statues of the old Scythians and Saxons? the cherubs and cherubims, the death's head and bones of our immediate forefathers? Do they form any section of the fine arts? The truth is, that the Saxon seems to be wholly uninventive, and perhaps the pure Celt too, although rather better than the Saxon. In what period of ages would the Negro races of Africa invent something superior to the Fetiches? Did the Egyptians ever go beyond the one form? not in the least. Look at their Memnon and Sphynx. An exact knowledge of form is the great point for the artist. Mr. Haydon gives an amusing definition of domestic and high art. "The power of representing things exactly as they are, constitutes the painter in domestic art; while that of restoring them to what they were at creation, constitutes the great painter in high art." This is his definition; it involves him in inevitable contradictions, refutes his idea that the Elgin marbles are works of high art, and leads to absolute absurdity. Worse than this, if worse can be, follows. "Form is the basis of all art, and a deep knowledge of the human form is the basis of knowledge of the forms of all other objects in nature, and a power of drawing the human figure as it ought to be drawn, the foundation of the power of imitating everything else a painter requires to use as an instrument to convey thinking." (p. 8).

If it be true that Michael Angelo spent twelve years of his life in dissecting, those years were misspent. The same remark applies to Da Vinci. I doubt the fact; Da Vinci's sketches of the bones as we have seen, are not after life, but memory—they resemble the bones in nothing but their grand outline—Cheselden's engravings are *fac similes*, and have nothing grand about them; but they are *fac similes*, and if a work of design is to be judged of by its resemblance to the object it is intended to represent, the sketches of Da Vinci and of Mr. Haydon—I mean, of course, the sketches of the skeleton—are mere trash when compared to those of Cheselden, or of the merest academical artist of the day. The art of painting scarcely approaches to high art; if it does so it is quite rarely: the *composition* of the "Last Judgment" —the works of Raphael—a work or two of Da Vinci's—modern paintings are sad specimens in general; so also are modern statues! the Duke's, for example, at Glasgow!

Having failed in showing that the knowledge of the Greek artists extended beyond the surface, Mr. Haydon proceeds in his second chapter to give us some idea of the amount of the anatomy required by the painter. That anything more amusing in regard to this art was ever put on paper we positively deny; his attack on the Reformers for destroying the existing works of art, the painted windows in cathedrals, are all good enough and just enough; but a word in passing as to what these destroyers did actually destroy. The works of the great masters of Greece had not reached England, much less Scotland; the works of the great Italians did not exist: what then did they destroy? mention a single work of probable excellence; a single work possessing the ordinary elements of good taste—what then did they destroy? the miserable daubs of our Saxon ancestors; the things called images, some of which still disfigure our churches, cemeteries, and cathedrals.* But to return to Mr. Haydon's anatomy, and to its importance to art, "high or low." His allusion to the influence of accurate drawing over the success of our manufactures appears to us both true and false; true, inasmuch as it has been proved that artists must be taught to draw, to design, in fact; but false, inasmuch as Mr. Haydon attempts to fix on the human figure as the only style worth teaching the artist. All this is pure nonsense, or if it really contain any reasoning, it can only be this, that as drawing correctly the human figure is the most difficult part of all art, so he who can do this well may hope to succeed in any other design. This is well enough and perhaps true enough, but to assert that there is any relation between such drawing and the sketches and figures of shawls, plaids, tapestry, or gown pieces, whether silk or woollen, or of "cotton wool," is downright folly. But let us return to Mr. Haydon's pictorial anatomy. I have already shown that Da Vinci knew nothing really of anatomy; nor can I find there exists any positive account of any great artist of modern or ancient times who did. First, we have an examination of the bones composing the human skeleton, not all of them of course; those of the face which we had thought amongst the more interesting to the artist, have been very sparingly touched. The whole examination, indeed, tells us that whilst writing it, Mr. Haydon was aware that nothing of all this was required by the artist, and that he was writing about an art he did not understand. Next follows an examination of the bones of the trunk and limbs; such an examination! There is the pelvis, os sacrum, os coccygis, os ilium, os ischium. What has become of the os pubis, Mr. Haydon? Could you not get a surgeon's boy to tell you where it is placed? or rather, could you not have taken up a common anatomist's manual, and learned from it that the bones you speak of here have no separate existence in the adult? You say you have drawn very frequently from the adult skeleton: how are we to believe you? If ever you had the pelvis in your hand, you must have seen that your description has no reference to it. This is much puppyism in all this, and a great self-sufficiency and conceit. Either you are a pictorial anatomist or you are not; if you be as you say, a pictorial anatomist, you might at least have learnt as much of the anatomy of the human body, as is acquired by a student of three days standing; yes, of three days standing, for your knowledge of the skeleton positively does not extend further, or rather not so far, for you are ignorant of the most common facts in the anatomy of the human figure—or, perhaps you did not think it necessary, just as many of your "compeers" cannot write, cannot spell, and can scarcely read: resembling in this respect a great number of our Scotch medical graduates.

Mr. Haydon's Latin is like his English: *pisiform* is translated "neat little bone!" The number of bones in each finger is not even hinted at, nor the remarkable differences their joints exhibit; the forms of these even in a general way are not even hinted at. His theory as to the cause of the afflicting deaths of Lord Castlereagh and Sir Samuel Romilly (a brain overcharged with blood) is not new. We remember hearing a surgeon of some influence now, (Mr. Syme), bring it forward, and explain thereby the effort of the suicide as an attempt merely to relieve the overcharged brain. It is a poor theory; the Parisian leaps into the Seine in quest of death; women drown and poison themselves in a variety of ways; men fire pistols at their own heads, all according to this theory to let the blood out and the cold air in. It will scarcely do.

Mr. Haydon admits at once that a knowledge of the deep muscles is not necessary to an artist any further than as they influence the external shape: still the question remains unanswered. Can the artist not draw what he sees? Now, what he sees directly is just the general integumentary

* This is no doubt a correct view of the subject of Genius, which seems to be dependent on, or at least connected with, a peculiar form of Head and Brain. But genius is not ability.

* The great error committed by Knox and the Reformers was, the leaving vestiges of the old "Rookeries." Grants of public money are now being issued for their *repair*, which means re-establishment. The "Woods and Forests" are at this moment repairing the Cathedral at Glasgow, with a view, no doubt, to the re-establishment, by-and-bye, of the "double-faced Janus," Episcopacy, within its walls. The civic authorities, on being questioned by a member of Council touching these repairs, at whose instance they were carried on, declared total ignorance on the subject. Worthy men! the re-appearance of the "Hydra of Privilege" within St. Mungo's walls troubled them not, so long as they touched not their ledgers and spinning jennies, their schools of design, and their designs for schools.

covering of the body; nothing more: no muscles, no bones, no viscera, nothing but integument and outline: let him learn to draw what he sees, and draw it accurately, faithfully; all the rest appears to be nonsense, or at least false science—a false view of the principles of art. The great defect, says Haydon, in the theories of Reynolds, Opie, Fuseli, as to what were the leading principles of a Greek standard of human form, was, that they had never dissected man or animal. Sir Joshua, who painted beautifully, but, it is said, drew ill, and who really knew nothing whatever of anatomy, recommends the artist to study carefully a great variety of forms, selecting what is best, and compounding the whole into one graceful figure. This is merely the ancient theory of Leusippus; it certainly explains nothing, seeing that it neither satisfies us as to why such forms should appear beautiful to the mind of the observer, nor why they were discovered by the Greeks. Misunderstood by all artists since, rejected by Michael Angelo and so many others, and unsatisfactory when attempted by the moderns—all these points are no doubt left unexplained by Sir Joshua's theory, but equally so by Mr. Haydon's anatomical theory. He give as an instance the suppositious one of finding 98 of 100 men flat in the hips; "all the hip muscles were compressed," and that two only had the full swelling of the hip (obliquus descendens). He says, we should prefer the form exhibited by these two—on the ground of their superior strength, we presume, for he can mean nothing else; development of muscle means strength of muscle—now *strength is not beauty*: a muscular form is not a beautiful form. Nobody ever called the Hercules beautiful: the real secret is, as we have already explained, that it is not the muscular but the *rounded* form which is looked for; the form which conceals the anatomy: the *juvenile form*; the form of *youth*, of ever springing and ethereal youth on which the human mind doats; inherent in our nature—ever looking forward—this makes the playful lamb be more looked at than the ewe; the gamboling colt; the tender half-closed rose; the *springing verdure*; the bloom of youth; the infantile human form: all, all are beautiful in a sense, but the human form alone is perfectly beautiful. Now, what has rendered them so?—the lineaments and features of youth. Mr. Haydon has some speculations as to what belongs to a species; this will never solve the great question of *abstract beauty*; the beauty of the Greeks; the beauty of the antique—unapproachable by human effort. The first sculptors seem to have been altogether unaffected by theory, appealing at once to the feelings; soon they discovered that drawing the form was regulated by three great principles, which, after all, may be reduced to one; but, admitting that they are three, the principle is not altered thereby. These principles have already been laid down in the first, second, and third papers of this memoir.

Much has been said about Sir Joshua Reynold's deficiency in drawing, and it has been ascribed to a want of anatomical knowledge, but with far more probability might it be ascribed to a defect common enough to thousands, namely, an original defect in the correspondence of the eyes and hand in the delineation of form. Sir Joshua seems, at no period of life, to have had a correct eye for "form." This was proved during his visit to Italy. Fuseli never dissected, and was slightly frantic; he never could clearly express his ideas. Opie never dissected—like many good artists he could neither read nor write, but was of great natural ability; a passage quoted by Mr. Haydon, at p. 181, from Opie, shows great power and truth, but it does not contain the whole truth.

"The prime object," says Opie, "is the re-discovery of the principle on which their works (those of the Greeks) are formed, which none of the moderns have attempted, comprehended, or suspected. The best of them have taken some favourite figure and used it on all occasions. Thus, in escaping the meanness and vileness of common nature, they confounded all distinctions of character and became incurable mannerists, insipid or extravagant, according to the choice of the model."

"These observations are remarkably just; Michael Angelo, for example, and Fuseli, who cannot, however, be well mentioned together, worshipped the torso. The absurdity of this is manifest; Fuseli's ignorance of anatomy appears to have been very great."—(Haydon, page 182.)

Haydon's and Opie's theory is "a judicious exaggeration of man's peculiar distinctions when compared to the brute;" this according to Opie and Haydon, was the secret of the ancients. Let the reader ponder well on the admissions of such a person as Opie; he avows that the theory of beauty of the antique had never been discovered to his day; now, has it been since? Has it been discovered in the anatomical theory of Sir Charles Bell and Mr. Haydon, and of the miserable twaddlers about Pictorial Anatomy who, supported by the London and Edinburgh cliques, formed their ideas, such as they were, from these distinguished men, snatching, at the same time, the bread from their mouths; a time-serving cold-blooded gentry in the mean time looking on, and affecting not to see anything misplaced in a scribbling apothecary! a general practitioner in the arts of physic and surgery holding the honours and place due to Sir Charles Bell! Looking on! not looking on merely but lending their effectual aid to crush Sir Charles and fine art with him, merely to gratify the vanity and cupidity of a thorough political hack and partisan. So much for art and its patrons in Britain.

Section 4.—Before concluding the Antique, it may still be useful to ascertain from the writings of Mr. Haydon, the artist who most of all has insisted on the necessity and importance of a knowledge of anatomy to the painter and sculptor, whether or not he and they who coincide with him in this view actually know anything of anatomy, beyond the grossest outline of the skeleton and the superficial muscles. Now, this may easily be shown. I shall mention a few points not selected but taken quite at random; as Mr. Haydon's anatomical knowledge is below criticism, it were idle seriously to refute it at any great length. Our readers may perhaps be inclined to think with us, that the very fact of Mr. Landseer knowing nothing of the anatomy of animals he so beautifully depicts is in itself a sufficient argument; and so I think it is; for *mutatis mutandis*, the remark is strictly applicable to men; but a prejudice of such standing is not to be overcome so readily; "the Buccinator muscle," says Mr. H. "comes from the common process of the upper jaw, the temporal muscle is inserted into the end of the lower jaw;" is this anatomy? it is absolutely inconceivable how clever men, from Da Vinci to Haydon have still persisted in their silly notion about the absolute importance of a knowledge of anatomy, their own words all the time belieing their statements. Here is Mr. Haydon's expression in regard to the throat, for conceited though he be, like so many of his brother artists, he is obliged to speak the naked truth—"the throat is complicated in its anatomy, but we have nothing to do with anything but the visible" (p. 119). Was ever anything more happily expressed in entire refutation of all the preceding 117 pages? and if he had but added, "take care and conceal from the spectator the slightest idea that there lies anything beneath the visible, any abhorred bones and muscles and sinews; any '*memento mori*'; any emblems of putrefaction and of frail mortality;" he would then have nearly embraced the secret of the high art of Greece."

Now, of the pomum adami, which he says projects on the surface of woman's beautiful neck, we caution the artist to express it as slightly as he possibly can, for it is a male character, and by so much as it is prominent in woman, by so much is her throat less feminine; therefore, we say again, take care and not express it too strongly: you had better leave it out altogether, or very nearly so.

He cannot express the most ordinary anatomical fact correctly; does this arise from affectation, or is it really profound ignorance? if from the former it is laughable, if from the latter it refutes his whole theory of drawing:—"In the notch of the ham-strings lie the great arteries, vein, and nerve of the leg;" now, there is *one* great artery and *two* nerves; but he cannot or will not state this simple fact. "Three great muscles go over the patella into the bump of the tibia," (p. 82). Now, there are *four*: he corrects this at page 84, knowing that he had been writing or speaking at random.

As Mr. Haydon's anatomy is deplorable, so his physiology is comical. The heel bone is the lever in the lion, and the panbone in man!! Was there ever such nonsense written? Mr. Haydon says, "I have studied feet which were never disgraced by shoe, where the great toe was free and distinct, and the second toe the longest always." Surely there is a deep error here: the second toe unquestionably is the longest in the *finely formed* foot: but you will not find it so in one of a hundred European feet; the wearing or not wearing shoes has nothing to do with all this.

That part of Mr. Haydon's theory which would have us believe, that for the human form to be beautiful, it must recede strongly from the brute, may or may not be true; it has nothing whatever to do with the sources of our ideas of beauty of the human form which we have seen are altogether instinctive, having no reference whatever to any reasoning process in the observer—to any association of ideas—to any comparison or antithesis: harmony is harmony, whether contrasted with discord or not—the negro is handsome in the eyes of the negress, and she finds favour in his eyes—he thinks and believes her to be beautiful: our pale skins he admires not, and symmetry, regularity of outline in the features, flowing looks, proportioned limbs, are to him and her perhaps matters of indifference. To deny that their forms are strictly human would be an untruth, and to say that we think them not fine because they bear some distant resemblance to the lower animals, it would be necessary to prove that this is really the source of our innate dislike to the other—but the truth is, that our dislike is innate, and the races will no more assort together, than the sheep with the antlered deer, the ox with the horse, the antelope with the zebra.

Mr. Haydon claims the discovery as his own of the extraordinary excellence of the Elgin marbles; they are indeed wonderful, and of surpassing excellence—but do they combine the ideal with nature, as he says? are they actually equal to "*the Antique*," which preceded them in creating in the mind that extraordinary feeling of unapproachable *Beauty?* that is the point: do they include within their qualities the *beauty* of the *Antique?* Now, that they do not is certain; as *imitations* of ordinary *nature*, occasionally a good deal elevated, they are admirable; they create surprise, pleasure, admiration, praise unbounded, but they go no further: they are not statues before which all the world bows down as before the *Antique*—adoring as supremely beautiful—never to be excelled—hopelessly faultless—unequalled—called divine by our instinctive feelings, giving utterance to language vainly endeavouring to express a sentiment beyond our comprehension. Now, the source of this admiration, and of this superior excellence in these Antique statues, has been already explained, satisfactorily we trust, in a former article—in the meantime we must not allow ourselves to be misled by Mr. Haydon, who ineffectually confounds excellence with beauty; perfection of figure with grace; proportions and form drawn from and placed by him in processes of bone and swelling muscles, with that divine and matchless outline which abjures bone and tendon and muscular projections; such parts, no doubt, are natural, to be found in most of the human race, and palpable and visible enough; but when nature made the beautiful, she knew how to correct (and yet not o'erstep her bounds) those very points which Mr. Haydon thinks admirable, and which she rejected as abhorred.

The first great object of the artist, whether painter or sculptor, is to represent *the visible*; 2d, to take care that he selects the visible which pleases; 3d, to attain high art, the visible must address itself to the highest taste displayed by the human mind; minds so constituted and so educated as to express simply what they feel, what pleases, what displeases, independent of all associations of ideas, (the ordinary substitutes and apologies for a want of a correct taste in music and the fine arts); thus the sublime and beautiful in art is instinctively pointed out, unhesitatingly, but

without a reason, to all the world. Mr. Haydon is evidently a phrenologist; to this his theory of beauty forces him; his theory is old; based partly on the exploded notions of associated ideas and fitness of things, but still lingering in such works as the "Theory of Expression of the Passions," and the "Lectures on Painting, by Mr. Haydon."

(To be continued.)

COURSE OF LECTURES ON THE THEORY AND PRACTICE OF MEDICINE.

Delivered by C. J. B. WILLIAMS, M.D., F.R.S., Professor of the Practice of Medicine, and of Clinical Medicine at University College.

We have hitherto in the special part of these lectures considered those diseases which may be called local as obviously having their first or chief seat in some one organ or tissue, and the amount of their general influence on the system, varies much in different diseases, some producing but little disturbance in other parts or functions, whilst others, as the more acute and important inflammations, cause great general disturbance of the whole system; and this general febrile disturbance, from being a symptom of a local disease, is called *symptomatic* fever. An inflammatory fever may cause great disturbance of all the functions dependent on the circulation, as secretion, excretion, &c., and if it affect a secreting organ it will disorder the balance of the secretions, and the blood will become deteriorated, and thus the whole system will be affected, but the disturbance is still sympathetic. The disturbance is particularly great when the inflammation is in the alimentary canal, liver, &c., as in malignant cholera, in which a number of the secretions are affected; this disease may indeed be looked upon as a link between local and general diseases, and the same may be said of rheumatism and gout, in which there is febrile disturbance distinct from the local inflammation, and often preceding it; the disease depends on a morbid condition of the blood, and is not fixed in any one place, but wanders about; still it cannot run its course without local inflammation.

In other diseases there is general disturbance following symptoms which are distinctly referable to the nervous system, as in tetanus, hysteria, and delirium tremens. In many diseases, the general disturbance is not proportioned to the local affection, being sometimes much greater, and sometimes less; thus in parotitis and tonsillitis there is a great amount of febrile disturbance, though the local inflammation is not important; and again in typhoid inflammations, the constitutional disorder is disproportionately great. The causes of these peculiarities are often some epidemic or specific influence which operates on the whole system, but particularly affects special organs, as in influenza.

Now if there are causes of disease acting on the system, and still affecting one organ especially, are there none which produce general disorder of the functions without essentially locating themselves in any one? We conclude that there are, viz., *idiopathic* fevers, because these occur independently of any constant local disease in one or other set of organs, and produce different diseases in different individuals from constitutional differences: they depend on a change in the system which causes general disorder essentially, and local disorder only accidentally. Still, it might be inferred that some organs would be more affected than others in different persons, and we find indeed that they generally cause some organs to suffer more than others, and very commonly our chief treatment has to be directed to these local effects, which constitute the chief peculiarities, and the danger of the disease. Fever appears to be essentially the result of some influence operating on the whole system, but affecting some functions more than others, and mixed up with complications; its true character is so frequently made up of other disorders, that we cannot understand it without being acquainted with the local affections, and therefore we have first considered these. Also, as a general fact, I may state, that although we assume that idiopathic fevers affect the system generally, and certainly no set of organs in particular; still it does not prove that one part of the body is not more affected than another, indeed the blood is probably the chief seat, and is obviously disordered; and inasmuch as the blood pervades the system at large, when this is diseased, the disease must be general.

There are certain common characters of idiopathic fevers.

The symptoms at the onset are generally chilliness, lassitude, various uneasy sensations, pulse small, and slow at first, surface cold and shrunk; and there is a certain amount of prostration—the vascular powers are depressed, and there are symptoms of accumulation of blood in the interior. This constitutes the cold stage of fevers generally. It is gradually followed by re-action, in which the pulse is accelerated and fuller, the heat of skin morbidly increased—appetite generally wanting—thirst great—secretion greatly diminished, and there is a general derangement of all the functions, nervous and vascular, and the pathological elements are all disturbed. These symptoms may continue for a time, and then at last subside, without there being symptoms of any one organ being affected more than the rest; and these cases may also prove fatal, and no material result of disease be found in any organ sufficient to account for death, thus differing from symptomatic fevers in which, after death, various lesions are found.

Many idiopathic fevers differ from symptomatic in the greater predominance of the typhoid symptoms; in these the pulse is weaker and smaller even from the first—the strength is more reduced, the secretions are more deranged, the tongue more furred and more viscid, and gradually becomes drier and dark—sordes form about the teeth, the appetite fails more—skin hotter and drier, though it may be less continued than in the inflammatory affections; the nervous functions are also more disordered. In the earliest stage there is apt to be stupor, vertigo, or syncope; and there is a general feeling of soreness, tenderness, or malaise. Sometimes also we have tremors, subsultus, deafness, loss of vision, and the sensorium is more manifestly disordered, as shown by the low muttering delirium and stupor, the person appearing to be obtuse and stupid; and, contrasting this with symptomatic fevers, we find the symptoms are in the last loudly complained of, and the sensations morbidly acute, as in rheumatism. The blood is also less firm in coagulation, or does not coagulate at all, and this in extreme cases is shown by there being ecchymosis, passive hæmorrhages, and a tendency to run into gangrene. Andral and Gavarret say, that the fibrine is deficient, and not the red particles, which are even sometimes apparently increased, whereas, in symptomatic fever the fibrine is increased, and the red particles diminished. In many idiopathic fevers there are peculiar and characteristic inflammations occurring after the fever, as in eruptive fevers, where the inflammations affect the skin, but other parts may also be affected, as the fauces and nasal passages, or the Peyer's glands of the intestines, as in one form of typhus, hence called dothinenteritis.

Again, they have a greater tendency to run a particular course than symptomatic fevers, and tend more to a spontaneous termination, hence generally there is a determinate duration of the disease, and the result is either recovery or death.

In all there is a certain struggle between the vital powers and the disease. This struggle sometimes occurs at regular periods, leaving the system free in the intervals, as in intermittents. In other cases, there is no distinct cessation of the disease, but it abates in violence at intervals, as in remittents. In others, again, the fever is continued; still there may be slight diminutions at times; but in both the last there is a tendency to a spontaneous termination at a certain time, generally between the tenth and twentieth days, and the termination is often accompanied by evacuations, called critical: sometimes the fever appears to have worn itself out, and there are no evacuations. The sweating stage of intermittents may be considered critical for the time.

The duration of idiopathic fevers appears to have very little relation to the treatment adopted, *i. e.*, we have very little power of cutting them short, our chief object, therefore, in the treatment is to prevent complications arising. This differs from the symptomatic fevers, in which there is a tendency to the destruction of some organ, and remedies can often cut short the disease, and remove the fever. Lastly, many idiopathic fevers differ from symptomatic in their causes being specific—endemic, epidemic, and infectious, and now ascribed to poisonous influences, conveyed by the air or some other means, hence affecting masses of persons generally, not individuals merely as symptomatic fevers do, the inflammation producing which generally arises from a physical cause. All idiopathic fevers may present certain common characters, depending on the different exciting causes which we have just mentioned; but the type depends on the constitution of the subject, &c.; the chief types are the congestive, the inflammatory, the adynamic, the typhoid or nervous, ataxic and the malignant. These may occur in remittent and intermittent fevers, but more in the continued, as in this all the constitutional functions are more disordered.

Congestive fever may arise from the person being plethoric, or from the peculiar nature of the poison, which appears to injure the vascular system more in these cases than in others. Such seems to be the type of the fever prevailing at present.

Inflammatory fever commonly occurs in robust and sanguineous persons, but sometimes it depends more on the character of the epidemic, and on the constitution, or the age; also, it is more common in the country than in towns.

Adynamic fever occurs in very weak subjects, or in persons whose vascular power has been exhausted by continued stimuli, or who are constitutionally weak; also, it may depend on the peculiarly depressing character of the epidemic.

Typhoid fever generally occurs in nervous subjects, but not always, and it may arise from the peculiarity of the epidemic.

Malignant fever arises from the great intensity of any of the preceding causes, thus in such cases, the immediate effect of a dose of fever-poison is to cause fainting, and so in cholera, &c.; in others there is a putrefactive tendency of the fluids.

There are other varieties, as the *gastric*, which usually occurs in persons with weak stomachs, and is accompanied with gastric derangement; so also, *bilious*, *catarrhal*, *cerebral*, and various others arising from the complications affecting particular sets of organs.

Intermittent fever or ague is particularly characterized by occurring in what is called a fit, but when occurring in persons for the first time, there are generally some *premonitory* symptoms, as slight feverishness, especially about noon, headache, lassitude, tongue white, appetite bad, feeling of biliousness, bowels constipated or relaxed, urine high colored and disordered, &c. The fever may last in this, its state of incubation, from four to fourteen days, and then the *fit* comes on, generally beginning with a sensation of cold creeping in the back, the features become pale and shrunk, surface cold and contracted, constituting the cutis anserina, nails and lips look blue, the pulse is small and quick. As this state increases, we have the slight convulsive action called shivering, which may be violent causing the teeth to chatter. This cold stage is accompanied often by a feeling of great oppression of the internal organs from the intropulsion of blood, there is dyspnœa, cough, constriction of the temples or headache, pain in the back, nausea, and sometimes vomiting, increased dulness over the liver, &c. The urine is diminished in its proper constituents, but not in its quantity.

Such are the chief phenomena of the cold stage; after it has lasted from half an hour to two hours, or even more, the hot stage comes on, the pulse becomes harder, heat returns to the skin, and first to the head, and often there is intense headache, throbbing of the temples, and even before the rest of the body is warm there is great thirst; the urine is scanty and high coloured; the skin is very red and hot, the temperature rising up to 104° or 105° Fah., and sometimes there is an increase of pain in the previously congested parts. This stage may last from three to eight hours, and then comes on the sweating

stage; the pulse becomes softer, fuller, and less frequent, the skin less hot and burning, perspiration gradually breaks out, giving more or less relief to the headache, thirst, pain, and all the symptoms, the secretions are increased, the urine, though not high colored, deposits a copious reddish sediment, and the patient is restored to apparent health, and is very weak, and remains exempt till the occurrence of another fit.

The next fit comes on in the same way, after an interval varying much in different cases, and different names are applied according to the rapidity with which the fits succeed one another: thus, if the fit come on again the next day, and occurs daily, it is called *quotidian*; in this the paroxysm generally occurs in the morning. If it recurs every third day, *i.e.*, after an interval of forty-eight hours, it is called *tertian*; in this the paroxysm is usually at noon; if every fourth day, *i.e.*, after an interval of seventy-two hours, it is called *quartan*, and here the fit is in the afternoon or evening.

There are many varieties of these, thus *double tertian*, in which there is a fit every day, but every other day the fit is milder and it occurs at noon; *triple tertian*, in which there is one fit every day and two every other day; *double quartan*, in which a slight fit occurs the day after the main fit; *triple quartan*, in which there is a slight fit on each of the two days of interval; *reduplicated quotidian*, in which there are two fits every day; this is, however, a remittent fever; other varieties are also named as *reduplicated tertian*, *and quartan*, &c. The more frequently the fits occur, the longer is the duration of each fit: thus, the quotidian lasts about sixteen hours, hence the interval is short; the tertian lasts about ten hours, and the quartan about six hours, and we determine the class to which any fit belongs by its duration, as well as by the time of occurrence. It is clear, therefore, that the quotidian is the most formidable. The different forms are mutually convertible; thus, if quartan becomes tertian it is worse, and *vice versa*, and we see these effects produced by the administration of remedies.

The cause being assumed to be the direct operation of a poison on a predisposed system, if the dose of the poison be strong and the body weak, the worst form (quotidian) occurs, and the fever may be converted into remittent, or even continued fever; *vice versa*, if the person be strong and the poison weak, the milder form (quartan) occurs.

In simple fever there are two powers in operation, viz.: the poison, which is depressing, causing the cold stage; and the re-action of the vital powers which occurs afterwards; variations of these cause variations in the type. In slighter cases there is a certain balance between the depressing force of the malaria, and the re-acting force of the system, and the fits are regular and the intermissions complete.

When the fever is more energetic the symptoms of collapse are greater; or some other cause co-operates with the poison, as cold, which is a depressing agent, and this may prolong the cold stage; or the severity of the disease may depend on the constitution; thus in delicate persons the re-action is weak.

Intermittent fever may be *inflammatory*; this occurs especially in cold districts, and in the cold seasons of warmer countries, and in persons of a sanguineous constitution, the cold and malaria appearing to produce a combined result; the amount of re-action in the last stage is excessive, and the congestion is converted into inflammation. In this form there is usually an intense cold stage, and the re-action is also excessive, and there may be various symptoms of excitement in the different organs, as vomiting, if the stomach is affected, dyspnœa if the chest, &c., and these symptoms continue during the intervals, and constitute complicated fever, but most commonly these are regular tertians or quotidians in their type.

Opposed to the inflammatory is the *adynamic* form of intermittent fever, which is attended with deficient re-action and the signs of weakness; the stages are less distinct and more irregular, and the intervals are not quite exempt from disease. There is faintness in the cold stage, the rigors which are the indications of commencing re-action, are not well marked; there is less heat and excitement in the hot stage, and in the sweating stage there may be a feeling of chilliness and weakness; the pulse is quick but not hard and full; the secretions are more disordered, the urine is dark colored and apt to decompose, the perspiration scanty and offensive, the countenance sallow, tongue loaded, and as the system is not relieved by the re-action, there is great liability to internal congestions leading to complications, which may lead to inflammations, and these greatly increase the danger and prolong the duration of intermittent fevers, hence the type is quotidian, or double tertian, &c.

The *complicated* form of intermittent fever is especially observed in persons living in malarious districts, and in whom the poison has previously debilitated the organs, also in those who are predisposed to any visceral disease, or it may arise in some cases from the excess of the poison; this is the malignant intermittent fever of warm climates, as Italy, &c. These exhibit confirmed local disorder, and at length structural disease of the organs, such as low gastritis, or hepatitis, or dysentery, or splenitis, &c.; the abdominal complications occur chiefly in the autumn, and those of the chest, pneumonia, bronchitis, and pleurisy, in the spring and in cold climates. The general symptoms of these visceral affections are obscured by febrile symptoms, and we must depend on the physical signs. When the complication is in the chest, the fever is generally less typhoid than when it is in the alimentary canal, but the continued oppression of the breathing may give rise to much prostration. Cerebral complications also sometimes present themselves, but more rarely. They may all be traced to congestions converted into inflammations by vascular re-action.

The prognosis of intermittent fever when simple and the cause is removed is very favorable; the cure is generally easy, but when complicated it is very obstinate, and sometimes very fatal, especially in the adynamic form which prevents the use of antiphlogistic measures. Even when it is mild, if the person is not removed from the cause, both structural and constitutional changes may be produced, without there having been any regular fits; the countenance becomes sallow, the skin bloated or wrinkled, the red particles of the blood deficient in quantity, and a state of general cachexia, with loss of appetite, disordered secretions, especially alvine and urinary, and often abdominal enlargement, and the individuals die early in a dropsical or cachectic state.

The *morbid appearances* in fatal cases vary with the duration of the disease, and with its form; in recent cases the only morbid appearances are, congestion of the internal organs, especially the liver, spleen, and the mucous surfaces; hæmorrhage sometimes occurs from the alimentary canal, and the spleen has been found even ruptured by the excessive congestion in the cold stage; in the intestines, besides the congestion of the mucous membrane, the follicular apparatus is much developed. In adynamic cases, the blood is found remarkably black and viscid, as in the Walcheren fever, in which the spleen was much enlarged, and resembled a bag filled with tar, and the blood in other parts was quite uncoagulable.

In inflammatory cases there will generally be the signs of inflammatory re-action in the lungs and intestines, hepatisation of the lungs, and sometimes ulceration of the intestines; but in other cases there may be no marks of inflammation, even where there have been symptoms of it during life.

In the more advanced and old standing cases, there will be various solid enlargements of the liver, spleen, and mesenteric glands, constituting ague cake; sometimes also other complications, as congestive diseases of the lungs, the kidneys, &c., with commencing granular degeneration.

We understand that many gentlemen who signed a petition, diligently hawked about, requesting Mr. Guthrie to take the chair at a public meeting, have recalled their signatures; seven gentlemen in Pimlico have recently done this in a letter to Mr. Bottomley.

AN ESSAY ON THE VARIOUS FORMS OF ASPHYXIA, OR SUSPENSION OF SOME OF THE PRINCIPAL POWERS OF ANIMAL LIFE, WITH GENERAL RULES FOR RESUSCITATION.

By Dr. Chas. Clay, Piccadilly, Manchester.

(*Written expressly for the Medical Times.*)

Prefatory Remarks.—In offering the following observations to the public on the nature, varieties, and treatment of Asphyxia, presented to us under the familiar term of suspended animation or (more properly) suspension of some of the principal functions of animal life, I have endeavoured to condense as briefly, and plainly as possible, the multifarious opinions as to the cause, practical treatment, &c., adopted by the best authorities of the day on this important subject; and without destroying either their interest or usefulness, to place before the reader, a selection of the best means, arranged in a style the most useful and easily adapted to the several circumstances to which individually, and collectively they may be found applicable.

By this means the reader will be enabled at once to refer to any particular case, when he will find all the directions necessary to be attended to, without having to make references to different parts of this Essay for items, that would not only cause a loss of time, at a season when every moment is pregnant with importance, but confuse the minds of the persons engaged in an act the most philanthropic and humane, and render the subject more complicated than desirable.

By placing the whole of what is necessary to be done in each particular case under its own head, some repetitions will unavoidably occur; but if the motives I have just expressed be construed aright, such will not only be found justifiable, but even necessary.

I have also borne in mind the necessity of adapting this essay to the comprehension of society generally, by freeing it as much as possible from technicalities, being perfectly aware how frequently the cases touched upon in the following remarks, have to be conducted to a successful or fatal termination, before a medical man can, by any possibility, be procured; and this too at a time, when a few moments' loss or gain is fatal or otherwise to the life of a fellow being. There are means too, used in the treatment of the various forms of Asphyxia, which deserve particular notice, having gained considerable popularity from custom and the generally prevailing ignorance respecting the subject, but which are nevertheless erroneous in principle, and injurious in practice; these will be spoken of after arranging what is imperatively necessary *to be done*, under the head of *what must not be done*. Cases of Asphyxia naturally divide themselves into those of an accidental or unlooked for character, and those of an intentional or suicidal nature, and I shall pursue the subject under inquiry agreeably to that arrangement. It would be difficult to say which of the above classes furnishes the highest quota (numerically speaking) of cases for consideration; the tendency of man to esteem himself "*sole proprietor of himself*," and seek self destruction as a refuge from real or imaginary evils, as well as those arising from accidental or unlooked-for causes, is unfortunately sufficiently prevalent to form an important item for national inquiry, not only in reference to reducing their number, but in advancing the best means of restoring those who are by accident, intention, or otherwise, placed in a condition to require them.

The first chapter on existing analogies between real and apparent death and the concluding one on the treatment of the dying and the dead, are in a great measure new subjects in treatises of this nature, nevertheless I hope their utility will be acknowledged on perusal. In my own opinion they are of deep importance to the humane, and worthy their especial attention, as well as strictly legitimate in an Essay of this description.

With these prefatory observations I shall now enter on the consideration of the various topics to which the term asphyxia refers.

CHAPTER I.

On the Analogies existing between Real and Apparent Death—Utility of the Inquiry, &c., &c.

"I know when one is dead, and when one lives;
She's dead as earth:—Lend me a looking glass,
If that her breath will mist or stain the stone,
Why, then she lives. LEAR.

It has not hitherto been customary to consider the differences between real and apparent death, with that of suspended animation, and I trust I shall be excused for the introduction of the subject, by shewing the importance of the connexion between them, which must also appear to every one on the slightest reflection. The many extraordinary instances on record, of resuscitation after long apparent death; of premature interments, and many circumstances exhibiting resemblances very striking to those of death, as sleep, syncope, catalepsy, eclamsy, suffocation, concussion, strangulation, drowning, intoxication, and mephitism, fully justify the introduction of a general chapter on this subject, preceding the subjects to be treated upon taken separately, as a warning to those employed in the exercise of humanity, not to relinquish their efforts too soon, or refuse their help for a time, in even the most apparently hopeless cases. It is true, many circumstances have been related of so marvellous a nature, as to lead to a doubt of their authenticity, but there are many others so well attested, that we cannot deny their general accuracy, particularly when connected with circumstances that have occurred in the experience of almost every person of mature age, and acute observation: sufficient will be established to prove the importance to futurity, as well as the best means of avoiding the errors and prejudices of former times, and to place this important subject on a surer basis than it has hitherto been. To discriminate between real, and apparent death, is not quite so easy as might be supposed; the many remarkable instances recorded, will prove how often the one has been mistaken for the other, not only by the ignorant, but by persons of learning and observation. Errors, arising from the want of power to distinguish properly between those really dead, and the many states similar to death, have been more frequent (as might be expected) in those countries where the interment of the dead takes place immediately life is extinct, as is the case in all hot countries, also Ireland, France, &c. Fortunately in England, errors of this nature are less numerous, the dead being usually kept some days, and in very many cases putrefaction having commenced; instances of premature consignment to the grave are extremely rare; but, as such have occurred, even in England, and the bare possibility that such might occur again in no way depreciates the importance of this consideration. In periods of epidemic and infectious diseases, the public safety has enforced the necessity of interment earlier than the usual customs of the country previously allowed, and it is to be feared many have been prematurely committed to the grave under such circumstances. The history of the Plague in London in times past is pregnant with instances of this kind, and perhaps the cholera of modern times has not been entirely free from such charges.

Before proceeding to lay down any directions on this subject, it will perhaps interest, as well as instruct the reader, to enumerate a few instances that have been recorded in respect to apparent death. Diemerbroeck relates a case, in which respiration apparently ceased for three days during an attack of the plague, yet the patient on being carried to the grave recovered, and lived many years after. Howard the great philanthropist states that many persons supposed to be dead of gaol fever, on being washed for interment, recovered.

In the reign of Elizabeth, a family of the name of Clopton, in Stratford-upon-Avon, was attacked by a contagious fever; one of the daughters, supposed to be dead, was buried on a bier in the family vault, according to the custom of those times: ten days after, the son died, and on opening the vault for the son, the daughter had left the bier, and was found on the steps at the door of the vault, having really died after her resuscitation in the vault, either from horror at her situation, or the want of food.* Vesalius the celebrated anatomist opened the chest of a corpse, and found the heart beating, for which he was condemned to death by the inquisition, and only saved by the interference of Philip of Spain. Bruhier relates a case of recovery from apparent death after the anatomist had commenced operations on the body; this person lived some years after. Winslow states that the Emperor Zeno, when his tomb was opened, was found to have devoured a portion of his own arm. And a similar circumstance is related in respect to the celebrated Duns Scotus. Granger mentions that the Earl of Pembroke, who died in 1630, on being opened for the process of embalming, raised his arm. In the reports of the Humane Society for 1787, a lady in Herefordshire is represented to have been restored to life, after interment, by the attempt of a thief to steal a valuable ring from her finger. Hippocrates mentions a case of fever to every appearance dead, that recovered during the customary ablution. Paul Zaccheus relates a case of long apparent cessation of respiration which recovered. Sydenham gives a case of a person being laid out for dead from the small pox who recovered, and lived many years after. Bruhier gives another singular case of a notary at law with his vicar, who had a severe fit of epilepsy, insomuch that his friends supposed him dead; and as it was customary to bury within twelve hours, the vicar insisted on his interment; from some noises heard at the grave, it was opened, when evident marks of violent struggling were visible, but the notary was *then* quite dead. The daughter of Laurens the American president, was laid out for dead, after an attack of small pox, when the washing and cool air restored her to life; the father had so great a dread of premature interment in consequence of this, that he willed his body to be burnt at his death by his friends: it was, however, just as possible to commit the same mistake in the burning as in the interment. Peu commenced the Cæsarian operation on the body of a supposed dead woman, to save the child before he discovered she still lived. Diogenes says, that Empedocles acquired great fame for restoring a woman after apparent death from hysteria. Pliny in his article "De his qui elati revixerunt;" states that Avicola's body was placed on the funeral pile, the flames of which restored him to life, but not in time to save him from a second death. I might mention many cases of recovery after being long in a state of asphyxia that have occurred to me during the last twenty years, but they will more properly come under the treatment of the various kinds of asphyxia. Lastly, I might mention the historical fact of Henry the Fourth, recovering from a state of apparent death, so as to reproach his son for his hasty seizure of the crown, giving birth to those beautiful lines:—

"By his gates of breath,
There lies a downy feather, which stirs not;
Did he suspire, that light and weightless down
Perchance must move."

Enough has been stated to shew how very necessary it is to be positively certain of death, before the rites of sepulture are allowed to take place. Many other instances might be cited equally strong, for which the reader may be referred to the Encyclopædia Britannica, Art. Premature Interment; and the works of Diemerbroeck, Hildanus, Bruhier, &c. Even admitting some of these statements to be exaggerated, they still afford sufficient proofs of errors of judgment; and when we view the striking similarity between the collapsed state of Asiatic cholera, from which many have recovered and death, I cannot feel much surprised at the extraordinary relations here alluded to. There cannot remain a doubt, that the sudden change of temperature produced by washing and laying out, as practised after death, with the cool air admitted by open windows, has often resuscitated individuals supposed to be dead from small-pox, which also might occur after severely protracted labours, when persons have been frequently seen in a state so near death, as scarcely to be distinguished from the dead. A case of this sort is related by Janvier in the Journal des Savans. Dr. G. Smith observes "in cases of precipitancy or confusion as in times of public sickness, the living have not unfrequently been mingled with the dead." He mentions the case of a woman restored to life at the grave side under his own eye. All such cases, however, go merely to establish the common fact, that people generally may be easily deceived; and from want of proper discrimination, many errors no doubt have arisen, but I hold it almost impossible if not entirely so, for any medical man of acute observation to be so far deceived as to allow premature interment; and I am also of opinion that the public generally would seldom, if ever commit an error of judgment in this respect, if they would attend to such rules as are within the grasp of the commonest intellect, and are as easily understood as put in practice.

I can assert with confidence, that there is no state similar to death which can possibly exist for any length of time without betraying some signs by which an intelligent person may distinguish it from real death, or in other words, respiration and circulation cannot really cease to exist for minutes together without real death taking place.

That these are the great functions on which life immediately depends, can neither be questioned nor considered new in doctrine; is it not said in the sacred volume "And in that very day his breath goeth forth, he returns to his earth; and in that very day his thoughts shall perish"?

A beautiful illustration of the dependence of life on the powers of respiration, and though the functions alluded to, may become so feeble as to require the greatest possible nicety to ascertain them, and to a general observer may appear entirely obliterated, yet they do exist, and on them life is still depending; the great question is, to what extent of feebleness these powers may be reduced and for what length of time without destroying the vital principle? That they may be carried on almost imperceptible for days together, the cases already quoted sufficiently prove. And to these we may add the many instances recorded of the Indian Fakeers, who after certain preparations allowed themselves to be buried in a state of Asphyxia, it is said, for periods varying from a few days to some months duration. Many of these statements are said to be well authenticated, whilst considerable doubt has been expressed as to others, it has however I believe never been denied that *for a few days* the Fakeers have the power, within certain bounds, of bringing themselves into a state of apparent cessation of the powers and functions of life, from which they are easily restored; without entering into the merit of the extremes of these cases, those of a few days will be sufficient to shew how feebly nature's work may be carried on by a little tuition feeble enough; indeed to escape detection and require no substance for its support and continuance for so long a period together!

Life has been defined to be that power of resistance given to organized beings against the surrounding physical and chemical changes by which that balance or power of resistance is overcome.

"Or ever the silver cord be loosed, or the golden bowl be broken, or the pitcher be broken at the fountain, or the wheel broken at the cistern; then shall the dust return to the earth as it was."

Then death ensues when the physical and chemical changes begin their operation, the first of which and perhaps the only one on which we can

---

*In a manuscript entitled Observations in Midwifery, by Percivall Willughby, about the date 1640 to 1670, who practised in Derby and Stafford, among many singular circumstances which are related is the following. "A strange, yet true accident, which happened at Ashbourne in Derbyshire;" Emma, the wife of Thomas Toplace, having been five days in labour," had a medicine given to her by a Doctor of Divinity, (Dr. Kettleby,) pretending some small skill in physic; "she was supposed to be dead, and was buried; but in consequence of noises being heard in the coffin, and some other suspicious circumstances, Mr. Pegg, a justice of peace, was consulted and "*the earth was cast off the coffin*," when it was found the woman was not only buried alive, but had given birth to a child, which was found between her knees. "Mr. Abraham Mercer took a certificate out of the parish register book, where it was thus recorded. —"April 20, 1650, was buried Emma, the wife of Thomas Toplace, who was found delivered of a child, after she had laine two hours in the grave."

implicitly rely individually, is putrefaction; all other evidences of death require to be taken collectively, to be of any value.

Although putrefaction may be truly regarded as the never failing indication of death, and the only safe test taken separately, yet it does not *perceptibly commence immediately after the cessation of the respiratory powers*: and as great difference exists in almost every case in respect to time, governed in a great measure by circumstances antecedent to death, considerable obscurity has been thrown over this part of the subject. The countenance of dead persons in many instances has remained for a very considerable time without apparent change, and in some the beauty of the complexion and expression of the features has been considerably heightened—the latter probably owing to the absence of pain in the last moments, allowing the countenance to assume its natural serenity; whereas in most cases, anxiety or pain produces an unpleasant cast of features. Or as has been expressed beautifully by an experienced writer on Medical Jurisprudence :—" as if the spirit, scorning the blow which severed it from mortality, had left the smile it raised upon the moveless features."

"Smiling as though some fly had tickled slumber,
Not as Death's dart, being laugh'd at."

The ancients were no strangers to these appearances, and they were accounted of no little importance by them; their poets declaring them to be favoured of heaven in their death. Thus Hecuba mourning the fate of Hector who lay without burial for twelve days, and was supposed, by the special favour of heaven to be preserved free from corruption.

"Now fresh and glowing e'en in death thou art,
And fair as he who falls by Phœbus' dart."

A circumstance the more remarkable, if true; as the body was dragged round the tomb of Patroclus attached to the chariot wheels of Achilles. From the length of time that many of the Grecian heroes were kept unburied after death, it has eben supposed to be a regular custom with the Greeks,(as the author of the Gentiales Dies states it to be) that bodies were usually kept seventeen days. Thus, Homer in reference to Achilles, says :—

Seventeen long days were in sad mourning spent,
As many nights did Gods and men lament,
But on the eighteenth laid you on the pile."

If this were true, premature interments would certainly be a rare thing in those days; but on searching the matter further, I find the number of days after death had reference to the rank and talents, military or otherwise, of the deceased. Achilles would of course, claim the longest period allowed. Servius names eight days; but of men of inferior rank it is expressed in the Argonautics thus ;—

" With three days' mourning they the funeral graced,
The last good office due to the deceased,
But on the fourth, they o'er his body raised
A stately tomb.

In reference to the poorest, however, Callimachus observes :

"Who knows what fortunes on to-morrow wait,
Since Charmis one day well to us appeared,
And on the next was mournfully interred.

The death of Hector then, and his being kept twelve days goes for nothing; he being in the hands of his enemies. Nor yet the noble remains of Alexander whose interment was deferred in consequence of the dissentions amongst his successors.

The ancients therefore were liable to premature consignments to the grave as well as the moderns. In this country the common custom allows of some days before interment; this is fortunate, and renders us less liable to error; not that this custom arose from a wish to prevent living internments, but from pride in the great, and powerful, to have their remains laid in state for some time; and in the poor from necessity, having their means, and convenience as to time to consult, it being an expensive item in a poor man's life: or it may be said to have arisen more out of respect to the deceased, or to circumstances in life, than to the philosophical view of waiting for the change by chemical decomposition, as a test against the possibility of interring a fellow being whilst yet living.

In many instances, the powers of life are so feebly carried on, particularly under the influence of disease, that the physical and chemical changes appear to encroach *on the living form*; at least, so striking is the resemblance, as to be mistaken for the putrefaction of death.

" My flesh is clothed with worms, and clods of dust; my skin is broken, and become loathsome," said the patient Job. " My loins are filled with a loathsome disease; and there is no soundness in my flesh ;" cried the psalmist David.

Under these circumstances it will be required that other evidences of death should correspond, and that full reliance can only be placed on even putrefaction, (conclusive as it may appear,) when there are the corroborative proofs of other circumstances to bear it out; still there is a possibility, that a person unaccustomed to such sights might be mistaken, particularly where extreme debility has previously prevailed, lending every appearance of death, and with difficulty distinguished from it.

PROGRESS OF FRENCH SCIENCE.

FROM OUR OWN CORRESPONDENT.

Paris, June 10, 1845.

On the Efficacy of the Mineral Waters of Bagneres de Luchon. By A. Fontan (d'Izaourt), M.D.—In this fragment of a work about to be published by the author on the mineral waters of the Pyrenees, it is stated that the chemical and physical characters of these waters are of a peculiar nature, as from the careful examination of upwards of three hundred different sources in Germany, Belgium, Switzerland, and Savoy, not more than eight were found to be analogous, and the others owe their resemblance to these to the decomposition by organic matter, of a sulphate, sometimes of an alkaline, but generally of a calcareous nature. After these preliminary remarks, the author proceeds—I To indicate the various diseases in which the mineral waters of Bagneres de Luchon may be taken with advantage. 1° Cutaneous affections, principally chronic eczema, local or general; lichen; impetigo; and even elephantiasis Græcorum and lepra in the first and second stages; 2° herpetic and scrophulous blepharitis; scrophulous ophthalmia; 3° scrophulous swellings of the glands, with or without ulceration; 4° scrophulous caries of the fingers, toes, carpus or tarsus, whether limited and superficial, or extended and deep seated; 5° necrosis of the ulna, fibula, radius or tibia; sequestra, which had existed upwards of a year were detached in less than a month; 6° syphilitic affections in the second and third stages as an adjuvant to mercury and iodine, and as a preservative against salivation; 7° chronic cystitis consecutive on blenorrhagia; 8° chronic rheumatism with swelling of the tissues around the articulations, as well as pseudo-anchylosis and muscular contractions resulting therefrom; 9° mesenteric tumours; the absorption of some several inches long was obtained; 10° vomiting which had resisted various remedies, but which was not caused by any appreciable lesion. 11° Chronic metritis, with sub-acute inflammation and chronic engorgement; when ulcerations exist, they must be healed previously, as the excitement caused by the waters is too considerable. The author witnessed many cases in which females, after having been married several years without having any family, on their return home became *enceinte*. 12° Intense neuralgia, especially neuralgia facialis and sciatica, when dependent on a syphilitic, herpetic or rheumatic affection. The patients were considerably relieved or cured, but previously to administering the water, they should be freely cupped or leeched, and emollient baths must also be had recourse to from time to time, even in the depth of winter. II. To give the details of several cases of the above-mentioned affections successfully treated. Finally, he concludes by refuting the opinions of MM. Boulay and O. Henry, contained in a memoir read before the Academy two years ago.

On Diseases of the Eye. By Professor Velpeau.—Though from what I have already stated it may be concluded that I have little or no confidence in the various remedies praised as specifics, still as it it necessary they should be known, I will in the present lecture pass them rapidly in review. 1° *Rheumatic iritis.* The remedies recommended are, *venesection*, but can this really be considered as a specific remedy ? Or is it admitted by practitioners, that affections of a specific nature ought to be treated by this means? Is it for instance, by bloodletting that the majority of practitioners endeavour to cure syphilis? No; for though proposed, still it is not generally adopted. *Colchicum and its different preparations.* Oculists have here been more consistent, as these remedies have long since been considered as specifics in rheumatism; it was therefore very natural that they should be prescribed in this variety of iritis. For this reason I did not reject them without giving them a fair trial, and in so doing I found that the preparations of colchicum were far from being constantly efficacious, and that the tincture in some cases in doses of ℈j purged, whereas, in others, ℈ij., ʒj., and ʒij. were necessary ere this could be effected; owing either to the time that had elapsed since its preparation, or to the idiosyncrasy of the individual. Be this as it may, it appeared to me to have no special influence on iritis. I prescribed it in the different varieties of the disease, in acute and sub-acute iritis, and I never obtained so beneficial a result from it as from calomel. *Turpentine.* Carmichael proposed this substance; the reasons why I think it ought never to be prescribed, have already been given, and need not be repeated. To conclude, it may be asserted that of all the remedies praised as specifics in rheumatic iritis none are of any utility. 2° *Scrophulous iritis.* As may naturally be supposed, iodine, from its efficacy in scrophula has been lauded in this variety, but in so doing, it was forgotten that this substance on account of its activity cannot be prescribed in such doses as act promptly, and that this result is absolutely necessary in a disease which is so rapidly developed: and as it can be given only in small doses, some time must elapse ere any beneficial result can be looked for. Is it not well known that months, nay sometimes years are requisite for iodine to act beneficially since the whole constitution must be modified ? Now iritis goes through its various stages in the space of a few days. Can iodine then be of any utility ? As a topical remedy I do not hesitate to affirm that it is useless if not injurious, and it is perhaps only in a very few cases of long standing iritis, that I have found it of the least benefit. To resume, iodine ought not to be prescribed in scrophulous iritis, the more so as this variety yields like the others to calomel and venesection; it may notwithstanding be conbined with these remedies to improve the constitution, in persons of a scrophulous taint. As to cinchona and acetate of ammonia, the mere mention is sufficient, as they possess no specific virtues.

There is a fact which from its singularity must not be omitted, viz. that topical remedies are never prescribed in the treatment of rheumatic iritis by the German school, as they considered them to be injurious, founding their opinion upon the following curious theoretical idea. " Since rheumatism," say they, " is caused by cold and moisture, no liquids ought ever to be applied to the eye." My own experience would lead me to adopt a contrary opinion, since I have found that some liquids may be used with advantage in iritis. But it must be understood that it is only those which act after having been absorbed, that are really efficacious. Thus, in the different varieties of iritis, ointments and collyria containing belladonna, opium, hyoscyamus, or mercury may be prescribed; they should be applied on the temples and forehead, since it is only by means of the circulation, that some of their principles are carried to the seat of the disease. Narcotics, cataplasms sprinkled with the liquor plumbi acetatis, collyria containing belladonna, lactucarium or opium ought never to be omitted. Finally in chronic iritis, bags containing camphor and aromatic plants may be applied on the eye. When iritis is complicated with keratitis or conjunctivitis, the collyria recommended in these affections should be employed, and then not only is the phlegmasia of the cornea or conjunctiva cured, but at the same time the intensity of the iritis is diminished.

Among the various remedies just enumerated, there is one which possesses a peculiar action in iritis, and the physiological influence of which on the iris, in its natural state, has caused it to be prescribed with advantage; I mean belladonna. As

on the one hand, in the normal condition of the organ, this substance has the singular power of dilating the pupil, and as on the other in iritis the pupillary opening is contracted, belladonna has been naturally recommended in this affection. In fact it is a very useful remedy, but ought to be prescribed with certain precautions which should always be borne in mind. Thus belladonna is not of use in every variety, nor in all the stages of this disease, and theory comes to the support of this opinion. In prescribing it, we seek to obtain the dilatation of the pupil, which cannot be done without causing the iris to contract, and for this reason it is counter-indicated in two cases: first, when the phlegmasia is very intense, as it will naturally increase its intensity, and secondly, when the part has lost its contractile power owing to the violence of the inflammation, as is frequently observed in acute rheumatism. But in the third stage of iritis, when the phlegmasia has diminished in severity, and whilst the pupil remains contracted, belladonna, employed in the mode which will be indicated when speaking of chronic iritis, may prove of service. It must not, however, be expected that the dilatation will be as considerable in iritis, as when the pupil is in its normal condition; in the latter the dilatation is marked, whereas in the former it is generally but slight.

The only remedial measures which remain to be enumerated are revulsives, such as setons, issues, blisters, cupping on the lower limbs, &c. These though useful can be considered only as accessory measures. In my next I shall terminate my lectures on these diseases by the description of chronic iritis.

On Imperforate Anus.—By Dr. Baraduc. In this article, the author after mentioning the divisions adopted by Lassus and Boyer, considers imperforate anus, with obliteration of the rectum, which he subdivides into 1° when the imperforate anus is only complicated by occlusion of the rectum, 2° when this malformation is complicated with obliteration of the intestine, coinciding with Boyer in the opinion, that when the malformation is not limited to parts situated near the anus, death is inevitable, but he thinks this would only be in the following cases, 1° obliteration of the rectum; 2° absence of the rectum; 3° termination in a *cul-de-sac* floating in the pelvis. *Case.*—Mrs. D. ætat 27, was confined of her first child on the 16th July, 1839. The infant, a male, was examined the third day after its birth by Dr. B., who discovered an imperforate anus; absence of the furrow which extends from the sacrum to the perinæum, buttocks forming a cone whose summit corresponded to the natural position of the furrow; the resistance on touching the parts was the same on all sides. The operation was absolutely requisite, the more so as the little patient vomited frequently, and had severe colic. It was therefore performed as follows in the presence of Dr. Renaud. The exact position of the coccyx and the tuberosities of the ischium having been ascertained, an incision of an inch in length was made with a narrow bistoury on the mesial line, about four lines posterior to the tuberosities, and as nothing escaped, the parts were carefully dissected to near an inch in depth, after which on introducing the finger, a round tumour was felt, and the bistoury on being plunged into it, allowed a small quantity of liquid meconium to escape. The opening in the rectum was then enlarged, so as to permit the egress of a thick slimy meconium, which was facilitated by several injections; finally, a tent was introduced to the depth of about two inches. Three weeks after, as the opening seemed to contract considerably, a second incision was made from before backwards; this, however, proved insufficient, and ten days after, a crucial incision was necessary. Nothing further worthy of note occurred; the child's health gradually improved, the faculty of retaining the fæces was, however, absent during the three first years of his existence; since then it has been perfect, the only inconvenience being that the little fellow is obliged to obey nature's mandate without any delay. The furrow is now visible, being caused in all probability by the traction of the rectum on the skin, and by the contractions of the levator ani. The boy now nearly six years old, is strong and healthy.—*Gazette des Hopitaux.*

On Œdema Neonatorum.—In a series of articles on the temperature of infants in the physiological and pathological condition, Dr. H. Roger, physician to the Bureau Central des Hopitaux, examines, first, those cases in which it is increased, and secondly, those in which it is diminished. Among the latter, one of the most interesting, and to which the author has paid special attention, is scleræma, or œdema neonatorum, and a brief abstract of his researches on this subject will here be given. In this affection the diminution of temperature is not limited to the skin, as in the cold stages of febris intermittens, or to the extremities, as in paralysis and during the agony in diseases of the heart; on the contrary, it is general, being reduced as much internally as externally. The thermometer falls several degrees, the animal heat seems to be attacked at its very source, so that sometimes ere life departs the heat is below that of a corpse. Thus, in twenty-nine cases the thermometer placed for five minutes under the axilla, in the fold of the arm, hand, mouth, or on the feet, was below the average heat (98°60) of healthy children from a day to a week old, and if in seven it reached from 95° to 98°, it was because the œdema was slight, and was complicated with bronchitis, enteritis, or aphthæ. In the remainder, the thermometer marked, maximum, 91½°; minimum, 71½°, about 27° degrees below the normal standard; and this diminution took place even when the child was affected with an inflammatory disease. With respect to the affection described by authors under the name of pneumonia, it cannot be that disease, since when it is present the heat is always considerably augmented; whereas here it is diminished, a fact which proves them not to be identical, and that the lesion is rather a congestion than a hepatisation of the pulmonary tissue. Pathological anatomy comes to the support of this opinion, for on examining the state of the lungs in these cases, they present none of the characters of pneumonia, but rather of congestion; moreover, there exists at the same time an analogous passive congestion in the brain, digestive canal, liver, pleura, peritonæum, and meninges; in short there is apoplexy of all the serous membranes, as sometimes in the lungs the congestion is carried to such an extent as to constitute pulmonary apoplexy. Sometimes the diminution of the temperature precedes the œdema, but is this always the case? To this question the author says he cannot give a positive answer, though he is disposed to say yes, on account of the intensity of the cold from the very first, and in general it is from this degree of cold that a positive conclusion may be deduced relative to the extent and violence of the œdema, for as this becomes developed, so does the temperature decrease. Thus, in one case, it fell from 90° to 75°; in another, from 82½° to 74½°; and in a third, from 89½° to 71½°, this last taking place in the space of four days. On the contrary, whenever the temperature remains stationary, and still more so when it increased, great hopes may be entertained of a successful termination. But what is the limit beyond which a cure is impossible? In two cases in which the children recovered, the thermometer marked from 89½° to 91½°; it therefore appears that life is in danger when the temperature falls 4° or 5° below the normal heat; and if the babe does not become a victim to the disease in its first stage, it is because the morbid action of the malady exercises its influence gradually. Again, is 71½° the extreme limit,—in all probability not; since doubtlessly the heat fell below this during the agony—which lasted upwards of a day—of one of the little patients. Edwards, by his experiments on mammiferæ, found the limit to be 55½°, and in birds 59°; Chossat, in mammiferæ, 65°, and other physiologists, 68°. The limit beyond which life seems to be impossible may therefore be placed between 71½° and 55½°. The pulse and the breathing decrease in a direct ratio with the diminution of the caloric. The pulse, examined in forty cases, was fifteen times upwards of 100; twelve times upwards of 80; and in thirteen below 80; in one only 60; whereas in 33 healthy children, the pulse was only thrice below 80. When it is so low, it is generally almost imperceptible The breathing, out of 39 cases—in thirteen was above the healthy average number (39); in the remaing 26 it was below, and in 6 it fell to 20, 16, and even 14, in the minute. In this disease the child seems to be changed into a cold-blooded animal, its temperature being hardly higher than that of the circumambient atmosphere, the difference being 11½°, 9¼°, and even only 6°. As to the cause, the author thinks it ought to be attributed to premature birth and cold; but is the diminution of the temperature, of the circulation, of the respiration, and of the power of motion, simultaneous or successive, and if successive, which appears first? From the facts established by M. Chossat's experiments, by hybernating mammiferæ, and by the author's researches, it may be concluded that the diminution of the caloric is the first, or at least the essential character, since the pulse and breathing may be normal and even increased in rapidity, though the temperature is diminished. None of the organic lesions which accompany dropsy in adults exist here: the liver is more the seat of a sanguineous congestion; the heart and the kidneys are quite healthy; nor could the author in the numerous autopsies he performed, discover the least traces of Bright's disease. Since, therefore, it is impossible to point out the precise nature of this affection, the denomination of *œdema algida* ought to be preferred, as it expresses its two pathognomonic characters. In admitting, however, that the principal cause of this disease is a lesion of the source of caloric, still it is impossible to state the relation between the serous infiltration and the diminution of the temperature, any more than it is possible in albuminous nephritis, to explain how the dropsy is dependent on the lesions of the kidneys and the loss of albumen. But in endeavouring to assign to œdema neonatorum its true character, the author candidly confesses that he has done but little to remove the difficulty attendant on the subject, since the diminution of the temperature is necessarily owing to some organic or functional lesion, which will be unknown until we are better acquainted with the source of vital heat.—*Treatment:* The various means by which heat may be developed on the surface of the body must here be employed, such as stimulant frictions, bags of hot sand; hot and vapour baths; cold affusion, if the diminution of the temperature is not too great. This must, however, be had recourse too at the commencement of the affection, when the thermometer is only 7½° or 9½° below the normal condition, and at the same time the child must be fed. It is by combining these two measures that M. Chossat, out of six cases, restored three to life; whereas in the 29 cases recorded by the author, only two were saved by the resources of nature. It may then be hoped, that by recognising the disease at its commencement by means of the thermometer, its cure may be obtained by this mode of treatment.

Academy of Sciences. Sitting of the 16th June.—M. Elie de Beaumont in the chair. Received.—On the Ganglia and the other Nervous Structures of the Uterus, by Robt. Lee, M.D., F.R.S., &c.—Remarks on Water, Swimming, Shampooing, Hot, Cold, and Vapour Baths, by M. L. Este, M.D., &c., with Statement of the Preliminary Measures and Reports on the Baths and Wash-houses for the Labouring Classes.—Proceedings of the American Philosophical Society, Vol. III.—Letter of Thanks from the Horticultural Society for the Comptes Rendus.

Experimental Researches on the Wounds of Blood-vessels, conducted especially with respect to the formation and organisation of the Clots in Arteries divided by a large transverse Incision, and the conclusions which may be deduced in Surgery and Legal Medicine. By F. Z. Amussat, M.D. Memoir read.—Before enumerating the conclusions which may be drawn from the facts contained in this memoir, the author indicates the differences which exist between his experiments and those of others who have studied the same subject They isolated the vessels from the neighbouring parts, so as to lay them bare, and be certain of what they were about; the author, on the contrary, always made a wound *without any previous dissection*, in

order to place the animals in a position in every respect analogous to that of a man when a blood-vessel is wounded. *Conclusions*—1° The spontaneous obstructing clot in arteries completely divided by a large transverse incision, is formed very rapidly, and, in a measure, under the eyes of the operator. 2° This clot is formed of the fibrine of the blood, and is kept in place by the external cellular membrane (the fourth) of the artery, not the sheath, as a superficial examination on the usual description of the structure of the arteries might lead one to suppose. 3° The central cavity of the spontaneous clots is very analogous to the craters of the sanguineous tumours described in a preceding memoir, and furnishes an important character, by which an artery masked by a clot may be discovered. 4° Contrary to the opinion of Jones, Beclard, &c., the artery does not need any foreign aid, since a clot may be formed at the extremity of an artery, which extends into the soft parts. 5° The clot is the more resistant and voluminous, according as the artery, and especially the cellular membrane was more or less stretched when the wound was inflicted. The practical conclusion to be drawn from this fact, is the utility of performing a certain degree of traction on the arteries before their divis on, so as to place them in the most favourable condition for the formation of solid clots, almost analogous to those observed when the vessel has been torn. 6° In pursuing the experimental researches on the wounds of blood-vessels beyond the surgical limits first intended, it was done in the idea, that they might, perhaps, be useful to forensic medicine: thus, when on a live animal the two carotids are divided at the same time, the medulla spinalis remaining entire, clots are constantly formed at the cardiac extremities of the vessels, their solidity and volume being in a direct ratio with the tension exercised on the vessel at the moment of its division. 7° On the contrary, when the arteries are divided one or two minutes after life is extinct, this being produced by a blow on the head, the division of the medulla spinalis, strangulation, asphyxia, &c., no clots are formed at the cardiac extremities of the carotids; or else they are very small, and not at all like those found in the divided vessels, when the death of the animal did not occur previously to the division of the artery, but was caused by hæmorrhage. 8° The cardiac extremities of the divided vessels are, therefore, the most important parts, since by examining them with attention, it may be ascertained with greater certitude than by the examination of the soft parts, whether the artery was divided during life or after death, either apparent or real. As may be seen from what precedes, important questions relative to physiology and legal medicine, are allied to the researches contained in this memoir, and which are the natural result of the other researches of the author on the spontaneous clot. They are, however, given with considerable circumspection, until they have been confirmed by other experimenters, and by facts observed on man according to the new ideas announced in this memoir, which is the more necessary, as hitherto the state of the divided vessels has been almost always overlooked in the recorded cases of legal medicine. Analogous facts when observed on man, demand to be examined with their consequences, under the treble relation to physiology, surgery, and legal medicine. This will form the subject of another memoir, which will shortly be submitted to the approval of the Academy.

On Arterioso-Venous Aneurism, with a Description of Two New Varieties of this Disease. By Professor A. Berard. Memoir read.—The author, after mentioning that as the communication between the vein and the artery constitutes the disease, the denomination hitherto employed, ought to be replaced by that of arterioso-venous aneurism, passes in rapid review the various authors who have written on this subject, from Sennert down to the present day, and enumerates the different species: 1° Simple arterioso-venous aneurism, formed by the passage of the blood directly from the artery into the vein, the latter being more or less dilated; 2° Spurious consecutive arterioso-venous aneurism, in which the tumour is formed in the adjacent cellular tissue. The circumstances which favour the development of this species, are the laxity of the cellular tissue between the artery and the vein—the obliquity of the wound—and the pressure generally performed for several days after the accident. Here the blood forces itself into the cellular tissue on the side which presents the least resistance, so that instead of offering a swelling on one side with the vein, and on the other with the artery, on the contrary it communicates by a single opening with the canal leading from the artery to the vein; 3° Two other varieties, as yet undescribed,* may be added. In one, the sac is placed on the artery opposite to the opening by which the two vessels communicate with each other, and in the other, the sac is placed on the vein; in the former the artery is transfixed and the blood flows directly into the aneurism; in the latter, on the contrary, it is the vein which is transfixed, and the blood passes through it into the sac. Two cases are recorded; one of a wound in the thigh, in which the instrument, after passing through the femoral artery, pierced the corresponding vein: the second was the result of the artery having been wounded in venesection. As to the treatment, the author advises tying the artery just above and below the wound.

New Experiments relative to the Removal of the Cephalo-Rachidian Liquid, and the Influence of the Posterior Cervical Muscles, and the Ligamentum Nuchæ on Locomotion. By Dr. Longet, M.A.M.—It is an opinion recorded amongst physiologists for the last twenty years, that the removal of the cephalo-rachidian fluid caused a singular disturbance in the locomotory functions. In order to permit the liquid to escape, the parts covering the occipito-atloidean space must be divided, and afterwards the dura mater and other membranes of the medulla must be opened. This done, if the animal, when all the fluid has flowed out, be left to itself you will see it stagger like a drunken man. To ascertain how far this opinion was correct, the author first divided the posterior cervical muscles near their insertion to the occiput and the ligamentum nuchæ, without touching the occipito-atloidean ligament, and consequently *without giving egress to the cephalo-rachidian liquid;* the result was precisely the same as what has been said to occur when this liquid is evacuated: secondly, part of one of the dorsal vertebra was removed; a slight weakness in the posterior limbs followed, owing to the division of the muscles, which was not increased by the evacuation of the liquid, nor were any of the characteristic movements remarked as when the muscles of the neck were divided. From these experiments it is evident: 1° That the cephalo-rachidian fluid is erroneously supposed to exercise considerable influence on the locomotory powers; on the contrary, that this influence is null; 2° That the division of the posterior cervical muscles and the ligamentum nuchæ produces in animals the staggering gait of a drunken man, and that, therefore, physiologists attributed to the loss of the cephalo-rachidian fluid, a result which depended on a very different cause, viz.; the division of the soft parts at the nape of the neck. The author concludes by stating, that in a subsequent memoir he will endeavour to explain the cause of this phenomenon.

On Cyanosis Neonatorum. By Charles D. Meigs, M.D., member of the American Philosophical Society, Professor of Midwifery and the Diseases of Women and Children, in Jeff. Med. Col., Philadelphia.—It is a well-known fact, that the obliteration of the foramen ovale does not take place until some, even twenty, days after the birth of the child, for were it to happen earlier, death would inevitably be the result, as the oxygenated blood would thus be prevented from circulating; therefore, while the brain, lungs, and other organs are perfect, the heart remains incomplete, as relates to after-life. From this circumstance it results, that a child born before the natural term is exposed to numerous dangers, resulting from the incomplete occlusion of the foramen ovale. These infants, on coming into the world, offer a blueish colour; their cries are weak, similar to those of a kitten; and, finally, all the signs of cyanosis neonatorum declare themselves, and increase until the little patient breathes its last, owing to the action of the venous blood on the brain. In order to avoid these accidents, the septum auricularum must be placed horizontally, and to obtain this, the child must be laid on the right side, the head and trunk somewhat raised, so that the weight of the blood may, by pressing on the valve, keep it shut. The professor states that he has saved by this method upwards of forty children, who otherwise would have died.

On the Formation of Fat. By M. Boussingault.—From the researches contained in this memoir, the learned academician concludes, 1°, that pigs, eight months old, kept at the ordinary food, contain more fat than they have received in the aliments. 2°. That pigs fed six months on potatoes do not secrete more fat than is contained in those roots. 3°. That in fattening (the experiment was tried on nine) there was more fat assimilated than was contained in the food. 4°. That food which, when given alone, has not the power of producing fat, has this quality to an extraordinary degree as soon as fat is mixed with it, although fat alone causes inanition. 5°. That the kinds of food which contain but a small quantity of fat are very rich in azotised principles. 6°. That in fattening geese, the quantity is superior, as M. Persoz stated, to that of the oil contained in Indian corn 7° That flesh is formed simultaneously with fat.

On the Treatment of Fistula Lachrymalis and Chronic Epiphora. By Paul Bernard, M.D.—In October, 1843, the author proved that the lachrymal gland might be removed without disturbing the sight in the least; and in the present memoir he gives the description of the *modus operandi*, adopted for the *first* time by him, in the treatment of fistula lachrymalis and chronic epiphora. This method consists in cauterising the ducts lachrymalis, and at the same time removing the healthy lachrymal gland, when consecutive lachrymation exists, owing to obliteration of the sac and the lachrymal ducts. The cauterisation of the nasal mucous membrane is performed superiorly with a more or less concentrated solution of azotate of silver; after which by an appropriate treatment and daily dressings, the cure is generally obtained in uncomplicated cases in the space of a fortnight, three weeks, or at the most one month. In complicated cases, the treatment is the same, but of longer duration, because general remedies must be combined with the local ones. The age of the patient does not necessitate any notable modification in the treatment. Cauterisation is performed with the intent of modifying the diseased tissues, rather than with that of obliterating the sac or the ductus lachrymalis, as attempted by Nannoni, Delpech, and some others. However, if notwithstanding these precautions, this accident occurs, and is complicated with constant lacrymation, hitherto considered as incurable by the ordinary means, the glandula lachrymalis must be extirpated even if sound, the more so, as numerous facts prove that it may be done without causing any injury. To resume, the advantages to be derived from the method here proposed are, 1°, a more *rapid*, more *durable*, and more *certain* cure than by the usual methods, and in general without leaving any cicatrix or deformity. 2°. An operation easily performed, and for which no particular instruments are requisite. 3°, Very little pain or inconvenience. 4°. More fortunate results. In the second part of the memoir, the author refutes the

* This fact is but the confirmation of the experiments performed by Dr. Amussat, recorded in three memoirs read before the Academy of Sciences on the 6th, 20th, and 27th of February, 1843, and from which he was led to admit the reality of several varieties of varicose aneurism, of which the principal are: 1° The *simple lateral*, formed by the communication of an artery and a vein closely united; 2° The *lateral with an aneurismal sac*, communication taking place by means of a sac between the vessels; 3° The *double aneurism, that is to say, an artery having been transfixed, an aneurismal sac is formed on one side of the artery, whilst the other communicates with the vein;* 4° The *direct*, when in an artery and vein completely divided, the communication takes place by a sac between them; 5° The *direct aneurism in cul de sac*, here the sac is formed at the cardiac extremity of the artery and vein completely divided.—G. DE B.

different objections that have been made against this operation.

On the Mode of Distribution of the Nutritive Fluids in the Animal Economy. By M. Milne Edwards, M.A.S.—The author in this memoir seeks to demonstrate that the existence of a circulatory system, composed partly of vessels and partly of hiatuses is neither an anomaly nor an isolated fact in the physiological history of animals. To accomplish this, he repasses the comparative study of the different ways by which the nutritive juices reach the various tissues in animals, and examines the mode in which the blood-vessels are developed in the normal and pathological state of the vertebrata. The results which he obtained seem to indicate that all are linked together, and that the mode of organisation, of which the mollusca form an example, is but one of the species of modifications by which the physiological development takes place in animals more and more perfect in their structure.

Mr. John Simon, F.R.S., addressed two works, 1° On the structure of the Thyroid Gland. 2° Physiological Essay on the Thymus Gland. The review of these works having already appeared in the *Medical Times*, I cannot do better than refer our readers to the number containing it.

GARLAND DE BEAUMONT, D.M.P., B.L., & S., &c.
Honorary Physician to the Spanish Embassy.

REVIEW.

Memoirs of the Life of a Country Surgeon. Reeve, Brothers.

This is a shilling pamphlet, written under some incomprehensible delusion by a Surgical patriarch, whose modest estimate of himself may be gathered from his motto "stat nominis umbra!" It is difficult to conceive what infatuation could have induced the writer to usher such a *brochure* on society. It is a chaos of jarring nothings—worthless aimless, without order, taste, or judgment.

NOTICES TO CORRESPONDENTS.

A. B. C., of Manchester *will be unable to practise, unless duly qualified when the New Medical Bill comes into operation.*

We have received a letter from M.D., *condemning the proposal of Mr. Muntz to write prescriptions, &c. in English, and recommending to the perusal of the profession a pamphlet entitled "Remarks on Physicians, Surgeons, Druggists and Quacks," published by Mr. Highley, as containing a clear exposition of the subject in all its bearings.* M.D. *is convinced that it would prove, not only highly injudicious, but positively injurious to our patients.*

AN OLD SUBSCRIBER—*May register as a Surgeon. The Bill leaves everybody now* legally *in practice in his present position, both in reference to title and practice. This will answer several of our correspondents' enquiries. The Council of Health will have full discretionary powers about foreign diplomas. By the law, as it at present stands, every one in practice before 1815, is as much a legal practitioner as the possessor of a hundred diplomas.*

FIDELIS.—*There is some little difficulty about a designation, but we fear the one suggested by our correspondent would be at least as unhappy as those now disputed about. The difficulty consists, not in the choice of a good name, but in its unanimous adoption, and we fear* "Medicion" *would commend itself as little to preference as* "General Practitioner." *Our correspondent's note is, however, so clever that we should be glad to hear from him occasionally on other matters.*

A Constant Reader.—*By the New Bill a graduate of the Edinburgh University can register as a physician without examination. He need not confine himself solely to the practice of physic. If he register as a General Practitioner he need not relinquish the title of doctor.*

We must refer a host of enquirers respecting the scheme of Purnes, *to the advertisement which appeared in our last number, which contains all the information we are able to give on the subject. For the future, our friends would save us much trouble by corresponding with the advertiser, who gives his name and address.*

A Medical Student.—*Try the Methodus Medendi, published by Dr. Mc Cormack of Belfast.*

A Student.—*In answer to the first question, there is no clause in the Bill affecting students, but there will* probably *be a bye law to permit all who have attained a certain point in their studies to pass under the regulations at present in force. On this all will depend, and without this, passing the College of Surgeons in Edinburgh or Dublin, if not effected before the Bill is made the law of the land, will be of no use whatever. There is nothing to prevent a surgeon from supplying his own medicines, provided he be duly registered.*

I. A. M. *is unauthenticated. We shall be happy to lend our humble aid in maintaining professional etiquette, but the difficulty of interfering in personal cases is considerable, and when we do interfere, it is necessary to have the statements on which we act well authenticated.*

H. B. H.—*The operation cannot be noticed unless we have an authorized report. We do not touch such cases of hospital misfortunes unless a public good is to be answered, and the facts are placed beyond doubt.*

Many correspondents are thanked for copies of memorials.

A Manchester Student *will find what he seeks in Dr. Golding Bird's* "Elements of Natural Philosophy."

Lionel Lincoln.—*Our correspondent has more to learn than he enquires about. A medical student is very unfit for his future duties who has not mastered the routine of an ordinary English education. If without more ado he persists in commencing his medical career, we think that for him the services of a private teacher, honourably distinguished, who may stand to him* in loco parentis, *must be far more useful than any public institution, though that institution be as distinguished as the one named.*

A Pupil *with the* full consent *of his master cannot do wrong by spending two years of his apprenticeship in the attendance on lectures in London. The Apothecaries Company have no wish to raise objections to this.*

Fides.—*Books on domestic medicine are mostly of a trashy nature. No particular work has fallen under our notice which we can recommend to our correspondent. The Practical Formulary is not published separately. Thirteen* Pharmaceutical Numbers *of* the Medical Times *have been published, and the index will not appear until the completion of the volume, which will comprise twenty-four numbers of the Journal.*

Unus ex Omnibus *will not complain we trust this week. His observations are much to the point, and are very serviceable.*

A Practitioner *should address to the source. Dr. Williams would doubtless feel flattered by his high encomiums and still more encomiastic censures.*

F. D. M. B. *says very truly, that persons do not like to have many questions put to them, and therefore submits to us not more than about a score. In answer to the main interrogatory, F. D. M. B. cannot too soon complete his medical education, and get a legal title to practise. Every year will, probably, enhance the difficulty. The best plan to pursue will depend on our correspondent's circumstances; but the school mentioned is, we believe, the most moderate in its terms of any we know. We are much flattered by the confidence of F. D. M. B., but he would do well to consult a medical friend, or his future lecturer on the many subjects he propounds to us. Our Pharmaceutical Number has no connexion with the Pharmaceutical Journal: we say it in justice to ourselves.*

Mr. Tranter's *note has been received, and shall not be overlooked.*

M. D. *will oblige by sending orders for publications, &c., to the Publisher, and Post-office orders to Mr. Carfrae.*

MR. WAKLEY AND THE LAW OF LIBEL.—Mr. James D. Protheroe, *Surgeon of Medhurst, writes, demanding a full account of the large sums of money which Mr. Wakley received when he established a College at Bridge-street, Blackfriars, for the granting of Certificates to all who might apply, and pay three guineas. He says he understands that about* £1,000 *was thus received. We must own that we should ourselves be highly gratified to publish a full and well-audited report of the sums received and spent in that celebrated transaction. The public asks it now just as much as before the late trial. The unfortunate Mr. Lambert, a fellow pupil of Mr. Protheroe's at Guy's, and the reporter of the Bransby Cooper case, Mr. P. saw, he says, three days before his death, and was assured by him that he died a broken-hearted man, and that,* not *from any excess of gratitude for favors he had received from Mr. Wakley. The case of Mr. Hutchinson, the ruined publisher of the* Lancet, *is then entered into: but as that is not, perhaps, if very strictly considered, a matter of* public *conduct, and has not been placed before the world as a subject of public record, it would be against our custom to dilate on it. Even on public matters, publicly recorded of public men, and treated on for the public good, the law of libel is, as our readers know, opposed to anything like a bold or searching analysis, except in the case of* reputable *characters. We may praise, but must be very chary in condemning. The Bill omits all reference to the Irish apothecary. By registering in the supplementary register he will, however, maintain all existing rights.*

Medico Chirurgicus *labours under an error in supposing that a General Practitioner who is an M.D. cannot retain his title with the customary practice. The Bill leaves him exactly where it found him in reference to all his present privileges. The supplementary register provides for it.*

A Surgeon.—*A vast number of correspondents have addressed us, on the subject of General Practitioners retaining their title of "Surgeon." Under the Amended Bill there is no doubt about the competency to retain the double title. All assertions to the contrary are so many misstatements. The only difficulty is about* future *General Practitioners.*

Mr. Hillier *has addressed us a letter with explanations, with the view of meeting any unfavourable inference that might arise from our late notice of a former communication with which we were favoured by that gentleman. Perhaps it is sufficient to say, that we wished to imply nothing that would affect Mr. Hillier as a sincere medical reformer and a gentleman of high professional honour.*

Mr. Levison's (of Brighton) *important proposal in reference to an Association of Surgeon-Dentists shall appear in our next number.*

Justitia *earnestly advocates a reform in private lunatic asylums. He complains that the London mad doctors have asylums with a hundred inmates and more, which they visit but once a week, and then for not more than half an hour each time. The proprietor, he says, should always be a resident; should be forbidden to mix pauper lunatics with others; and should be careful as to the character of his keepers. The whole subject is important; and one which if postponed, we certainly do not overlook.*

Erratum.—At page 240, for "*Dr. Alexander, Member of the Academy of Glasgow,*" read "*Dr. A. M. Adams, Member of the Faculty of Medicine, Glasgow.*"

THE MEDICAL TIMES.

SATURDAY, JULY 5, 1845.

This is true liberty, when free-born men,
Having to advise the public, may speak free.
EURIPIDES.

THE Medical Bill is put off again to Monday evening, and immense will be our surprise if it is not then put off for ever. *The work of Medical adjustment is, we fear, for another man and for another time.*

The last Amended Bill, on the whole, is not unsatisfactory to the Profession. While in Ireland and Scotland no voice is raised against it, in England (with the exception of about a dozen officials gracing the College of Physicians, and twice as many encumbering that of the Surgeons) there is hardly a Member of the Profession not heartily in its favour. The few who were deluded into a partial opposition by some absurdly impudent falsehoods and calumnies, have recently discovered their mistake, and the unanimity of support the Amended Bill which now obtains is as perfect as (in a Profession usually so divided) it is wonderful.

Sir James Graham knows this. He feels that the support he so boldly bid for as a Medical Reformer, he has got. The Home Office is crammed with grateful memorials; every M.P. but the unfortunate "*gentleman*" for Finsbury, is charged with commendatory petitions, and before the House and the country Sir James Graham at last stands the successful statesman who—baffling every unfavourable augury—has mastered the difficulties of Medical Reform, and secured what nobody expected for him—the satisfied support of a whole Profession. *He has but to speak the word to pass a good Bill!*

Yet this is the fortunate juncture—we are told —which a great Minister uses, not forthwith to do the act on which his fame and fortunes depend, and which performed will win him universal gratulations, but to enter into a haggling negotiation, with the monstrous object of making his measure as unsatisfactory and unpopular as possible consistently with not having it actually opposed! His Bill frightens him with its excellence and success, and therefore, the rumour goes, has it been postponed in Parliament week after week, in order that deteriorations to abate to the lowest point the exuberant satisfaction of the Profession may be foisted on it! A formal series of negociations have been maintained, it is said, with the National Association during the month, the whole *unsuccessful* drift of which has been to get their consent to his deforming and mutilating what cost him so much toil and humiliation to lick into decent proportions!! Surely Sir James is under some misleading spell. Brodie must again have been administering his philters!

We make every allowance for the Minister's position; it is most arduous; but he must allow us to tell him, that he is not *lessening* his difficulties by the *dangerous* course he is now said to be taking. Medical legislation is encompassed with difficulties, but Graham's self-created difficulty of trying to do justice to the Profession, and, at the same time to *satisfy* the Medical Corporators, is far more arduous to surmount than *all* the others together. It is an *impossibility*. A good measure pre-supposes necessarily the dissatisfaction of those who profit by its want, and precisely as a measure abates their dislike, does it secure ours. If Sir James Graham, therefore, shrink from carrying out his own proposal, at the very moment when it offers him the greatest triumph of his legislative life, as certain now, as it was hopeless a few months since, —if he thus shrink, we say, because three dozen interested London Practitioners decline to give him their *imprimatur*,—our respectful suggestion is— "Drop the matter at once. Cease the useless attempt to reconcile right and wrong. If you aim to smooth away the objections of both sides, your success—apart from deception—must be an inert, meaningless, and useless thing, that nobody will thank you for! To have an active, beneficial, efficient measure, you must wholly fling overboard one of the parties. To *please* all is impossible, if you will *do* something. No bill *can* cajole both sides into acquiescence which is worth the acceptance of either. Besides, you have altered enough already. You have happily reached the point that can be *most* satisfactory; every step you recede is a step removing further from support. A grave alteration in the present stage of the proceedings would be a breach of honorable engagement to those who support you. They help your Bill on the faith of its present clauses, and you give them another! Time likewise will be required to consider a new proposal. You have yourself established the just principle, that the Profession's voice should be heard in Parliament on each of your propositions, and you cannot make grave alterations without again referring the Bill to our further consideration. How do this now, and pass the Bill this Session? In one word: the Profession supports your Bill as it is,—justice, common sense, consistency, every interest you have, require that you forthwith pass it!

We can conceive no more idle attempt than that of at once giving the General Practitioners a College, of which they can honorably be members, and yet pacifying the Corporators in Lincoln's-Inn-Fields. The Councillors want what nobody in his senses can give them. Those worthy gentlemen care not a fig for the General Practitioners themselves; their whole anxiety is to retain the expenditure of the ten thousand a-year, derived from conceding a *nominal* fellow-membership to men whom practically they deride and maltreat as "Gallipots" and "Dabblers." Give the ravenous Council their prey of ten thousand a-year, and the General Practitioners may go "and welcome" to the "College of Physicians," the College of General Practitioners, or any other college they please! And does Sir James Graham fancy that the General Practitioners will be so false to their own order, and to the essential interests of their College (which—as new and unhonored—will want all the support they can give it) as to hand over, under one false pretence or another, ten thousand a-year to a rival college for doing nothing, or what is next to nothing, something that nobody wants? Does he suppose, that the twenty or thirty thousand Practitioners of England are to be legislated for as if they were so many cattle travelling this needless road, and that, just to pay toll to some dozen or two dozen persons, with whom, in common sense, they have actually not a particle of connection? We tell him, the proposal cannot be worded in such a fashion, whatever his ingenuity, that it will not be palpably ridiculous. Incorporated in the Bill, it would make it society's laughing-stock. The best title he could give his measure would be—"a Bill to perpetrate all kinds of nonsense, that the Council of the College of Surgeons may have ten thousand a-year for doing nothing!"

But unconsciously, in our anxiety for the integrity of the Bill as it now stands, and in a sincere desire to save the Minister from the indignity of any new remodelling of a measure even now sufficiently remodelled, we are hurrying into hypotheses which are as baseless as they are unjust to Sir James Graham. We have made the mistake of supposing, that the suggestions of "the insane Council" had taken a mind prisoner, which is not off its guard when approached by more wily assailants, and almost fancied that wishes from *them* were commands to *him*. This is far from the case. Sir James Graham has taken a step, and knows as well as we do that the care of his own character requires him not to recede. He has pledged himself to give *coute qui coute*, an independent College of Surgery and Medicine to the General Practitioners, without a single limitation or check to their emulative endeavours to raise it even higher in scientific note than the older Colleges, its rivals. He has said in so many words—"the College of Surgeons shall have what it asks—its Pure Surgeons; that of Physicians, its Pure Physicians; for the mass of the Profession excluded with insult from both, I will build up a National Faculty!" The scheme is magnificent; let it be carried out in a spirit akin. Sir James knows well that to lend himself to changes in an Act of Parliament, which would fetter scientific competition, which would coerce scientific enterprise, and put a badge of shame and inferiority on the shoulders of the great bulk of the Profession, and on whose high and *unsuspected* respectability and *unsuspected* skill, depends so much of the happiness of society, would be to lend himself, not to an act of statesmanlike polity, but a deed of imbecile infamy. The General Practitioners of England, and their cotemporaries in Ireland and Scotland, are at this moment the reservoir whence flow on the nation nearly all the blessings of medical attendance, and it is on their labours that the character of British Medical Science for the next century will depend. To stamp on such men a legislative brand of inferiority and incompetency, and to cramp, to confine, by Act of Parliament their scientific labours, would be an atrocious injury to human advancement—a hideous cruelty to the very best portion of our citizens, and a tremendous mischief to the whole of society. It would condemn any Minister attempting it to everlasting contempt.

Fortunate for us is it, that at this critical juncture, when the corporate wrongdoers are exerting such wonderful activity and adroitness to deprive us of a boon all but in our reach, we can turn with so much of hope and confidence to the Committee of the National Association. They have achieved for us great services. More await them: we believe in their recent negotiations with the Minister, they have maintained the high and self-sacrificing spirit of independence and dignity the profession expected from them. Need we tell them that they must maintain it still, unfalteringly, unflinchingly, heedless alike of threats or promises? The Bill does not give enough as it is. We cannot, therefore, afford to take less. The new College must start well; or must not be started at all. No new Apothecaries Hall under a better name will nearly approach the mark. With the organization that now exists, the profession, if true to itself, can command its own terms. If it fail this year, it must succeed the next. No timid compromises, therefore, could be tolerated for a moment. There are not a hundred persons in the profession to stand by a fettered or dependent, or semi-privileged Corporation. The course of the Association is therefore clear. The support they possess is not one of men but of *principle*. The straightforward, the fearless, the uncompromising course they have hitherto pursued, must be continued to the end of the chapter. For once the gift horse must be looked fully in the face. The Corporate mace must be gold—not gilt. Though placed in their very hand, it must be rejected as a worthless bauble, if it bring with it but a high sounding vassalage. At such an epoch all the Committee's excellences are lost if they rise not to another—self-abnegation. It may, perhaps, be that as the *Times* put it, "*the pear is not yet ripe.*" But on this point, as on all others, we repose that confidence in the perfect integrity and good sense of the committee which all their great labours so justly earn for them. They *feel* that they act under a serious responsibility, and know that so perfectly *independent* is the support that the profession gives them, that to fall short on one grave point would be to dismember the Association in an instant, and make the Committee as powerless as any other seventy-two Medical Practitioners. They are now passing through a trying ordeal; but sure are we that they will pass through it unscathed, with redoubled claims on our gratitude and support!

So fond are mortal men,
Fallen into wrath divine,
As their own ruin on themselves to invite—
Insensate left—or to sense reprobate.—MILTON.

WE are happy to announce that the Council of the College of Surgeons are not only beginning to see the error of their ways, but are making some small shew of practical repentance. We understand—indeed, we know for a fact—that at their last Council Meeting they resolved to petition the Crown (in the name of the "College" of course,) for a Supplementary Charter, in the hope of being enabled to make all Members of twenty years' standing "*Fellows*," and to change the absurd order of precedence that now obtains among those that are Fellows. We are, of course, delighted at this *prospect* of change. So also will be the Profession. But do we step forward one inch from our serried ranks to receive it? Do we abandon one particle of our phalanxed organisation? We surmise not. The change—*if it actually come*—is a boon, though a poor one. We give *it* a welcome. Do we, therefore, give the *donors* thanks? Yes; but the donors are not the Council of the College, but the Committee of the Association! To the twenty-one we owe the Charter;—to the seventy-two we shall owe the Amendment. The new improved Charter—if we get it—will be a SURGICAL SEPTUAGINT. The generosity of the Council is just the size of their *fears*; and we should be mad diplomatists if we declined to give constant sustenance to such useful friends. The Council should never be left without a terror, till we are left without a grievance. The only real repentance they will shew us, will be a death bed one. In the agony of expected annihilation they may do us justice; but relieve them of their fears, and the Corporators of 1845 will be the same Corporators they have shown themselves in all preceding years. The time when justice and sound policy would have appeared in the graceful shape of generosity is gone by. They threw their Members into hot water to give themselves an increase of miserable patronage; they have allowed them to remain in hot water during two years, without extending to them anything better than gibes and libellous abuse; and now, when the losses they sought to throw on others recoil on themselves, they fancy that if they replace about six per cent. of their victims in the position that is their legal right, they are to secure for themselves a vote of indemnity, and a fresh lease of corporate importance! We tell the Council they make a grievous mis-reckoning. The time for great gratitude for small mercies is gone by. They do quite wrong to fancy that their "boons" will be misunderstood. Their terror-bred virtues are our merits—not theirs. We have ourselves to thank and heartily for their slow-budding excellencies.

A tremendous lever certainly is the National Association. Let it but stand true to the Profession, and the Profession true to it, and a new era in Medicine awaits us. The work of regenerated Medical Government is yet but in its beginning. Refuse us the Bill we want if you please, but let us preserve the Association in its integrity, and before three years we shall have a still more favourable measure. With the Bill as it is, we will effect immense improvements; emasculate it so that we refuse to co-operate in it, and in a few years we will do even more! Every year adds increased potency to our principles; and the time rapidly approaches when a Ministry will find it dangerous to resist them.

If the Council of the College could read the signs of the times, and really sought in their Government something of the just and generous, they would propose a scheme made after a different fashion to this "boon" of doubling or trebling the number of their "Fellows." They would say, "The General Practitioners are upheaving hourly in numbers and respectability; a merely surgical or a general practice, instead of being a matter of grade, has become solely a matter of personal convenience. Physicians *sometimes* will not be Surgeons, but all surgeons are forced by the tide of opinion and fact to be Physicians; the profession, under one name or another is composed of General Practitioners; and those General Practitioners, who add Pharmacy to their calling, are just as scientific and accomplished General Practitioners as the Andrews, and Thomas', and Listons, who do not: with the advance of English medicine it would be as politic and just to cut down our Council to its oculists, because we have our Guthries, our Tyrrels, our Travers, and our Scotts, as to restrict it to some two or three dozen more, on the pretence of some equally absurd speciality. To maintain the insulting distinction is absurd, unjust, perilous: abandon it, and we give harmony and peace to the Profession: we attach to us nine-tenths of the medical men of Great Britain: we win the merit of making Medicine indebted to Surgery for the greatest boon she has ever received in England, and while giving our peculiar art the high distinction of taking Medicine under her protecting and encouraging wing, we secure for ourselves the celebrity of being at the head, not of a fraction, but of the whole profession!"

What a magic is there in a justice which knows no sordid restraint of personal interest—no corroding tie of class bigotry! With a little elevation of mind, how small a sacrifice, after all, would be required, not only to relieve the Council from their well-founded terrors, but to put them in a position far better than any they have yet occupied. But what their good sense will not achieve, our continued organization may. When the New College has only to await the sign manual to start into vigorous existence as the Great National Faculty, the reckless governors of a magnificent institution, all but ruined by their bigotted ineptitude, will capitulate at discretion. We shall be able to dictate to them our own terms, simply, because they allow to pass unused the precious time when they might all but dictate them themselves.

We are pleased, then—nay, delighted—with the small improvement offered us. Though trifling, let us still hope, that the Council may not recoil from it, as from the other improvements contemplated some time since, which they were noble-minded enough to shelve, just to spite the *Medical Times*. We have no ill-feeling against the Council, though for its ability and wisdom, we entertain anything but a profound respect. For the sake, however, both of the Council and the Profession we are sincerely glad to see that new leaf turned, which we have always held to be inevitable. After some Cassandra warnings against the *coming* Charter, we prophecied so far back as October 14th and 21st, 1843, (when by an odd coincidence both that document was granted, and the brother of the "silent" Mr. Wakley received a government appointment of nearly £2000 a-year), that it "was not in the nature of things that the Charter could last. If the General Practitioners were even twice as untrue to themselves as they had been, it would yet be impossible that this childish piece of corporate legislation could survive the next medical parliamentary enactment!" The prophecy seems near its realization, and with the same armed hostility for a few months longer, we shall have the speedy fulfilment of the other promises which the present aspect of medical politics so clearly holds out. Much that is good is nearing our grasp; but if we succeed in clutching it, let us never forget, that we have none to thank but ourselves.

Here's freedom to him that would read,
And freedom to him that would write:
There's n'ane ever feared that the truth should be heard,
But they whom the truth should indict.
BURNS.

There are one or two points in the late action of Mr. Thomas Wakley against ourselves, which should not be allowed to pass without notice.

In the ordinary course of law, the "inquiry" would have taken place before the Sheriff's Assessor and a good jury. The expense would not be considerable, and as that gentleman had never been a fellow Member of Parliament with Mr. T. Wakley, like the Lord Chief Baron, in whose court the Plaintiff had fixed the trial, it was the more desirable to us that the ordinary routine should be gone through. Mr. T. Wakley thought otherwire, and got the case moved back to the more expensive court of the Lord Chief Baron, on an *affidavit* that it was intended to introduce "other publications" in evidence, on which important points of law would arise. The trial came, and not a single other publication was referred to! Not an effort was made to support the affidavit; not a scrap of evidence was adduced about "other publications!" So much for an *affidavit!*

But so chary of evidence, so wary of using a witness was Mr. T. Wakley, that he did not venture to produce a single person to speak to his impugned reputation, or to controvert a single point alleged in the letter. The law forbad us to justify—did it forbid him to falsify? If not, was there not one respectable witness producible to give him a good character in open court? We should have liked much to have had that respectable person's cross-examination. No such opportunity was afforded us.

Mr. Wakley's counsel felt it necessary to undertake to deny that his client was a libeller. But how stands the case? From the *verbatim* deposition of the "unnatural crime," which ornamented the first number of the *Lancet* to the perfidious publication of Lawrence's infamous libel which so recently transpired, Mr. T. Wakley stands out the lowest, the most unprincipled, and vulgar libeller that the present age has witnessed. Yet this is the man, who in the words of the *Bristol Journal*, of Saturday last, brings an action against us for "suggesting to him the means of clearing his character of infamy!" Was audacious inconsistency ever carried to a higher pitch?

But we have done with the case. Mr. Thomas Wakley may take our word for it—he must feel it himself—the *denouement* we have so long prophecied has arrived. During the last three years agitation for Medical Reform, he has been intrusted but with half-a-dozen petitions; and even the one hundred and forty Medical residents of Finsbury have shown their distrust of him, by transferring, the very last week, their petition to Parliament to the care of the member for Lambeth.

A QUERY.

(BY A CORRESPONDENT.)

IN the event of the Bill being postponed to another session, *i. e.*, abandoned for ever, and the independent incorporation thrown again among the incertitude of a future day, a question will arise—where does the fault lie? Four months' since, and the Government annihilated in

intention the General Practitioners as a class. The scheme was to select a few who might be elevated to the rank of "*surgeons*," and to depress the rest to a level little if at all above the druggist. The Association grew in power; their influence told with the Government. Medical light no longer streamed exclusively from the Corporations —and in auspicious May the General Practitioners' Bill was announced, and promise of a new era was given. The Colleges were paralysed; and with perfect union among General Practitioners, a Bill realising the anxious expectation of a quarter of a century would have been passed before they could have scarcely recovered from their surprise. There *was dissension;* that dissension may lose us the Bill: in that case, on whose head will devolve the terrible responsibility?

There happen moments when even a disreputable person—powerless for good—may exercise, by fomenting discords, much mischief! Let that discreditable person be taught the full infamy of his triumph!

SOME REMARKS ON THE LATE DUEL CASE.

By an Old Army Surgeon.

The case of Mr. Seton has given rise to a second, viz. the *Times v. Mr. Liston.* The "Thunderer" attacks the "pure surgeon" and "renowned operator;" he replies dictatorially and peremptorily; he defends his operation (if not the *diagnosis*); lays down a rule or two of practice, which do *not* apply, and winds up by assuring the public, through the *Times* (for I hope they published his letter to them), that besides being a first-rate pure surgeon and cutter, he is also a very good medical man or physician, evidently preparing the way for a claim to a seat or niche in the New College of General Practitioners. Now, in all this, Mr. Editor, there is a wandering from the real *matter* of discussion, which I apprehend to be this—was the *diagnosis* or judgment, in respect to the nature of the wound inflicted, *correct* or *not*? The question of operation or no operation, is included in that. Permit me, an Old Army Surgeon, also a Civil Surgeon and Physician, and one who has seen a good many difficult cases, as well in surgery as in physic, to offer a few remarks on the points which I believe to be of most interest in this already complex discussion.

It is admitted—1st, that Mr. Seton received a wound from a pistol-ball (I follow Mr. Potter's narrative), which, entering "in the upper part of the right thigh, a little above, and in front of the great trochanter of the femur, crossing the abdomen or belly, passed out about the middle of the fold of the left groin." An occurrence, by no means unusual in gun-shot wounds, immediately followed; I mean "a rapid hæmorrhage or bleeding, described as florid, and in large quantity, issuing *per saltem* or in jets at both wounds, but more especially through the opening by which the ball entered, springing to the height of two or three feet from the wound." Now, as *no surgeon was present* I am at a loss to understand how matters can be described so minutely by *non-medical men.* As no medical man *was present*, how comes it that all this is described so minutely and scientifically? Was Mr. Jenkins, or some other person, looking on from behind a hedge, affecting not to see anything, nor anybody, and yet so critically and nicely watching the progress of events? I shall return to this curious part of the evidence by-and-bye. Passing it over for the present, I find that a Mr. Jenkins appears soon after on the scene. Now, here I ask a plain question or two, which, I trust, some person or other, possessing the due information, will have the kindness to answer;—was Mr. Jenkins an army or naval surgeon? Had he seen active service? How many cases of gun-shot wounds has he had the charge of? Was there, during the whole duration of the case, a *single surgeon present who was familiar with gun-shot wounds?* You must be well aware, Mr. Editor, that with such cases Mr. Liston is not, *cannot be familiar*; their varied accidents and changes are nearly unknown to him. I request your readers, then, to bear in mind, that Mr. Seton *seems* (for I do not pretend to know the services of the surgeons who surrounded his death-bed) to have been in the hands of those who had never treated gun-shot wounds, at least to any great extent. Arrangements like this I have seen before, with, generally speaking, the same result, namely, confusion, over-anxiety, and embarrassment. But, to return to Mr. Potter's narrative.

Mr. Seton was wounded on the 20th of May; on the 27th, a pulsating tumour appears over the right femoral artery; it increases daily somewhat, until the evening of the 30th, when the patient is first seen by Mr. Liston; at this time, the *sloughs* in the track of the ball had *not separated.* Every army surgeon who has seen practice knows, that his patient is never safe until that happens. Here, then, we have a pulsating tumour over a very large artery, on the 10th day after the receipt of the wound, and the *sloughs* have not yet separated. The whole question, at that moment, amounted to this—(I shall endeavour to state it as clearly as I can):—The blood filling the tumour, either came *from the femoral artery at first*, or it *did not.* If from the femoral artery, Mr. Seton would have died on the field, and the surgeons who attended Mr. Seton from the commencement ought to have known this. The responsibility, then, rests with Messrs. Jenkins, Stewart, and Mortimer, and if these gentlemen are not army or naval surgeons, who have seen service, and gun-shot wounds, then the responsibility and the unhappy results lie with those who called them in. I repeat, a wound of the femoral artery by a pistol ball, sufficient to give rise to an "*instantaneous, rapid, and severe hæmorrhage*," would have proved instantly fatal, and the medical attendants ought to have been aware of this.

On the 30th, or ten days thereafter, Mr. Liston is called in; he refuses to operate that evening; he does so next day, seemingly against his own judgment. I say seemingly, for the difficulties besetting his diagnosis were considerable. Still, he ought not to have operated; no army surgeon of experience would have countenanced the operation. Another operation proposed was, the opening of the tumour. Now, in doing this, the surgeon must necessarily have encountered the track of the ball, in a sloughing state, at the time. The risk of this must have been apparent to all medical men.

It appears, then, that the fundamental error was an erroneous diagnosis, formed by the surgeons who preceded Mr. Liston in the treatment of the case, and the adoption of their view by Mr. Liston, who, acting on their diagnosis, performed an operation which caused Mr. Seton's death.

Again—resuming the narrative—we find, that Mr. Potter was not himself present at the *post mortem* examination of Mr. Seton; this was conducted by Dr. Allen. The principal facts brought out by Dr. Allen, as condensed by Mr. Potter, are as follows:—1st, the wound was entirely, and throughout its whole length, subcutaneous, *a fact, which ought to have been perfectly well known* to the medical attendants, *from the very commencement* of the case, but which they, for the first time, ascertain when death has closed the scene. A blunt-pointed probe, passed in the trail of the wound, would have proved this fact—the first which ought to have been made out. Mr. Potter's extract however, although extremely judicious and well-written—does not suffice, on so material a point as the *post mortem examination of the wound*, and I beg leave, therefore, to call your attention to an extract or two of Dr. Allen's account of the matter. I do this with reluctance, and had originally determined not to do so, but the scantiness of Mr. Potter's details must be my excuse for going back to the original evidence of Dr. Allen.

In the *Times* of the 16th or 17th ult., I find Dr. Allen's verbal report, for such I suppose it was, to the coroner, during the inquest. I have looked over it with the greatest attention, and failing to find in it any of the more important facts mentioned in Mr. Potter's account of the case, I naturally resorted to the rest of the evidence, which I have again read over. The conclusion which forcibly presses itself upon me, is that singular discrepancies exist in the medical evidence given before the coroner, and that he (the coroner) and his court accepted evidence which was by no means trustworthy. Some circumstances, bearing on the propriety of the view taken up by the medical attendants are well and clearly remembered, and stated; others of equal importance are either omitted or forgotten. The appearances of the wound are not minutely described by Dr. Allen; his is not, in fact, nor does it bear any resemblance to a minute anatomical description of the passage of the ball. We are thus left to conjecture where Mr. Potter picked up those minute particulars as to the original condition of the wound. But why did he not furnish some other particulars, such as the condition of the clothes, and whether any portion had been carried in along with the ball?—or whether the ball itself was found?—what caused the abscess which appeared in the left groin? &c. Surely, the coroner might have brought out some of these facts. But the truth is, it is equally difficult to understand how the non-medical evidence is made by Mr. Potter (Mr. Liston's assistant) so scientific, and the medical evidence before the jury shows itself so unscientific.

The letter of M.D., addressed to the *Times* on this subject, is below criticism. The writer has not the slightest idea of the difference between a *wounded artery* and an *aneurism*, and he speaks familiarly (resting his opinion on that of Dr. Allen) of such aneurisms as this of Mr. Seton's being frequently cured "by absorption," meaning, of course, by "pressure;" but, even if he had said so, he and Dr. Allen too, are, I think, incorrect. I defy them to produce a single instance of an aneurism of a large artery, produced by *a gun-shot*, ever having been cured by pressure. The cases of an artery wounded *by gun-shot*, and by the touch of a *lancet*, are quite distinct, but he does not comprehend this. A gun-shot wound is, more or less, a sloughing wound. *Pressure* cannot be applied to such a wound until the sloughs have separated. He talks also of the great "fatality of such operations, and their formidableness;" no doubt, under some men, amputations prove extremely fatal operations; so does lithotomy, yet such operations must occasionally be performed. Mr. Liston's great error was his having formed an erroneous diagnosis; in this he was assisted, no doubt, by those who preceded him. No urgent circumstance existed when he operated, saving *one*,—the necessity of his

speedy return to London, where his practice awaited him. He was sent for to Portsmouth *to operate*—most unhappily for himself and for his patient, he allowed himself to be influenced by the impatience of the attending medical men. This is all.

The whole case, then, amounts to this,—it was Mr. Liston's duty to have taken *everything into consideration* for himself. If the medical men previously in attendance on the case were old army-surgeons of high standing, and of *great experience*, he might have been excused for his acquiescence; as it was, I think Mr. Liston might have said to them, "Gentlemen, here is a case of superficial gun-shot wound—skin deep, and no further. You think that the ball grazed the main artery in its passage across—that it opened it, giving rise to the first bleeding. In that case, the operation you talk about might be reasonable, but this opinion is an erroneous one, inasmuch as Mr. Seton would not have left the field alive had the main artery been then and there opened; but you think that a *large vessel* near the main trunk may have been opened; but *there are no large vessels there.* This opinion must, therefore, also be unsound. The only large vessels (deep epigastric and circumflex) lie much deeper; therefore, the ball would not have touched them; if it had, there would have arisen other troublesome symptoms, especially deep subfascial swelling, serous engorgement of the limb,&c. Your opinion, then, gentlemen, as to the *necessity for immediate operation*, must be erroneous but if you insist on it, I shall give you the responsibility: I cannot operate, contrary to every teaching of science, and every suggestion of sound diagnosis." Had this been Mr. Liston's language to these persons, his position with the public would now have been very different; as it is, he must bear, at least, a large portion of the obloquy of having performed an unnecessary operation, causing the death of a fellow being, and raising the accusation of being a person who, though of great operative ability, is yet liable to commit terrible errors, as to the *quando, locus in quo et quibus auxiliis.*

TRANSACTIONS OF LEARNED SOCIETIES

Royal Medical and Chirurgical Society, June 24, 1845. Dr. Chambers, President, in the chair.

The following papers were read :—

On the Frequency, and on some of the Causes of Pericarditis, with incidental observations on the frequency, and on some of the causes of various other internal inflammations. By John Taylor, M.D., professor of clinical medicine in University College, and physician to University College Hospital.

Frequency of pericarditis.—The author has found one case of severe pericarditis, as distinguished from the very slight forms of the disease, to occur in about every eighty of the physicians' cases in University College Hospital.

Pericarditis was four times as frequent in the fatal cases as in all others taken indiscriminately, for it was found sixteen times in the bodies of 355 patients, in all of which the heart was examined; old adhesions of the pericardium were found in one out of every sixteen bodies, and white spots or patches in one out of every four bodies.

Causes of Pericarditis.—The causes were examined in thirty-five cases of the more severe forms of the disease; nearly two thirds occurred in the progress of acute rheumatism, and nearly one third in connexion with Bright's disease. Besides these causes, the author has found the following only, viz., extension of inflammation from the pleura in one case, and from the liver and diaphragm in another. A third case occurred in connexion with cyanosis and malformation of the heart.

Nearly all the cases occurring in persons previously in good health were found to be associated with acute rheumatism, whereas nearly all those occurring in persons in bad health were complicated with Bright's disease.

The author has observed some form of morbus cordis in about half the cases of acute rheumatism which he has treated in University College Hospital. Pericarditis of considerable severity occurred in about one in twelve cases, which proportion is nearly the same as that found by various writers, with whose observations a comparison could be made.

Valvular Disease was found in about half the cases of rheumatism. This amount is nearly the same as that observed by various authors, but most writers either state, or imply that these cases were examples of *recent endocarditis*, and consequently they make endocarditis to be very much more frequent than pericarditis in rheumatism. The author of this present paper is uncertain how many of his cases of valvular disease were recent. He believes that the diagnosis between acute endocarditis and old valvular disease in acute rheumatism, is in many cases impossible, and in a large proportion doubtful. He has found signs of valvular disease which he supposes to be of old standing, in all physicians cases, taken indiscriminately, in a proportion so nearly approaching to that found in cases of rheumatism, that he considers the greater number of cases of valvular disease found in rheumatism to be of old standing, and that the frequency of acute endocarditis has been over-rated, and perhaps does not much if at all exceed that of pericarditis.

With respect to the circumstances under which cardiac inflammation appeared in rheumatism, the author found that metastasis occurred in none of his cases—the rheumatism was of the *fibrous* variety, as distinguished from the capsular, in every instance; pericarditis was not more frequent, but it was more intense and more fatal in severe, than in mild cases of rheumatic fever. The heart was more frequently affected in the early stage of this disease in young subjects, and in a first attack than in the opposite circumstances. Venesection had nothing to do with the production of inflammation of the heart in any case. Some writers appear to think that pericarditis hardly ever occurs except in connexion with rheumatism; others believe that the causes are in many cases unknown. The author has found a satisfactory cause in every case, and he believes that the two grand causes are acute rheumatism and Bright's disease. Both these appear to produce inflammation of the heart and of other organs in the same way ultimately, viz; by a morbid state of the blood; we may expect therefore to find pericarditis in connection with other blood diseases, such as the eruptive fevers, typhus, erysipelas, &c. Instances of this kind are recorded, but the only cases belonging to this class seen by the author was one of pericarditis with *cyanosis.*

Pericarditis has been long known to occur occasionally as one of the secondary inflammations produced by Bright's disease; but the frequency with which it is met in these circumstances appears not to have been hitherto suspected. The author believes that Bright's disease in its advanced stage has as great a tendency to produce inflammation of the heart as acute rheumatism has. It is true that acute rheumatism was more frequently the cause of the pericarditis in his cases than Bright's disease, but this may be due to the greater frequency of rheumatism than of Bright's disease. From a comparative examination of fifty bodies in which advanced disease of the kidney was found, and of 142 bodies in which there was no disease of the kidney, the author found that acute pericarditis was met with in one in ten of the former, and in one in thirty-five of the latter class, and that acute endocarditis was met with in one in twelve of the former, but only in one in seventy-one of the latter. Hence it appears that inflammation of the heart was much more common in cases with, than in those without renal disease; and also that acute pericarditis was met with as often in cases of advanced Bright's disease, as in cases of acute rheumatism.

Account of a Case of External and Internal Cephalhæmatoma Complicated with Fracture of the Right Parietal Bone, in a Newly-born Infant. By Chas. West, M.D.

The author details in this paper the history of a child, aged sixteen days, on whose right parietal bone there existed a swelling presenting the ordinary characters of sanguineous tumor of the cranium, or cephalhæmatoma. This tumor had appeared on the third day after birth, and had progressively increased; the child's health, however, continued undisturbed. Slips of plaster were applied so as slightly to compress the tumor, which, under this treatment, ceased to enlarge. The child continued quite well until the eighth day after this treatment had been commenced, no alteration having been made during this time in the plaster originally applied. At the end of this time, without any apparent cause, she was attacked with vomiting, and convulsive twitchings of the muscles of the face. On the ninth day, general convulsions occurred, which returned early on the tenth when they proved fatal, the child being twenty-six days old at death.

The tumor on the exterior of the skull presented the ordinary characters of external cephalhæmatoma. The author in describing it, takes the occasion to make some remarks on the nature of the hard ring which surrounds these tumors. He mentions the existence of a fissure in the parietal bone, and of a large collection of blood internally, betwixt the dura mater and the skull, in a situation nearly corresponding to that of the external tumor. He gives a minute description of this effusion, and calls especial attention to the reparative process which was going on at the time of the infant's death, consisting partly in the heaping up of bone around the tumor, and partly in the deposit of bony matter between the two layers of the dura mater.

The author next assigns reasons for believing the fissure of the parietal bone to have occurred during labour, and not to have been produced by injury after birth. He likewise inclines to the opinion that the internal effusion was not the result of the escape of blood effused originally on the surface of the cranium, through the fissure into its interior, but thinks it most probable that it took place at the same time as the external effusion, and from similar causes.

The variety of recorded cases of internal cephalhœmatoma, of which only eight have been described, and particularly the fact that no other instance has been related, in which the process of cure of internal cephalhœmatoma has been observed, are the reasons which have induced the author to present this case.

The paper is concluded by some remarks on affections of this kind, suggested by the peculiar features of the case he has detailed.

Two Cases of Anæsthesia and Loss of Motory Function of the Fifth Nerve, by James Dixon, assistant surgeon to the Royal London Ophthalmic Hospital.

This paper contains reports of two cases of anæsthesia and loss of motory function of the fifth cerebral nerve, attended by remarkably different symptoms. In one case, the eye on the affected side became inflamed, and vision was destroyed by a deposit of lymph in the pupil, anterior chamber, and substance of the cornea; the same morbid changes taking place in the eye, as follow the division of the fifth nerve in Magendie's vivisections.

In the other case, complete anæsthesia had existed for almost a year and a half, and yet there was not the slightest inflammation of the eye, nor any opacity of its humours.

In this latter patient, careful experiments were made, to ascertain what effect had been produced upon the tongue in respect to feeling and taste.

Both were perfect on the right side. On the left, all that part of the tongue which is anterior to the papillæ vallatæ was utterly deprived of taste and feeling, while both these senses were unimpaired in that portion of the organ to which the lingual branch of the glosso-pharyngeal nerve is distributed.

Diseases of the fifth nerve appear to be more frequent on the left side of the body; for out of forty-six cases (recorded by English and foreign

pathologists) twenty-nine occurred on the left, and only twelve on the right: while in five patients, both nerves were affected at the same time.

Case of Fungus Hæmatodes, by Henry Blenkinsopp, Esq., of Warwick, Member of the Royal College of Surgeons, communicated by J. G. Perry, Esq.

Abel Bonsor, aged 13, a pauper, fell from a gate and injured his shoulder in July, 1843. After some weeks an enlargement made its appearance in the left arm near the inner margin of the deltoid, and the boy began to suffer from darting, lancinating pains in the tumour. It rapidly increased, but the patient's state of health prevented any hope from amputation. Near the end of January an alarming hæmorrhage took place from an ulcerated opening. This was followed by great exhaustion, and the patient died on the 12th of March.

The body was examined on the 14th. On making sections of the tumour, considerable resistance was offered to the scalpel by the walls of numerous cells which formed a great portion of the tumour. These walls were composed of a fibro-cartilaginous substance, and the cells contained encephaloid matter. The disease seemed to have been developed in the periosteum, the cancelli and general texture of the humerus being perfectly healthy. The disease extended to the scapular region, the muscles presenting a liver-like appearance, but the bone was not implicated. The lungs contained tubercles in all three stages. The liver also contained tubercles, and a cyst of hydatids.

The author concludes by briefly alluding to some points in this case worthy of notice, viz; the absence of fungus, the complicated form of the disease, and the healthy condition of the bones.

Case of Excision of the upper end of the Femur in an example of Morbus Coxarius, by William Fergusson, Esq., Professor of Surgery in King's College, London.

John Clark, æt. 14, suffered for fifteen months from hip disease, and in February 1845, was in the last stage of hectic. The head of the femur was displaced on the dorsum ilii, and could be felt by the finger passed into a large sinus connected with the disease. The limb on the affected side was between four and five inches shorter than the other, and much distorted by flexion at the knee and hip. There was no indication of disease of the bones of the pelvis, and the head of the femur seemed the principal cause of suffering.

On the 1st of March 1845, the author made a longitudinal incision on the hip over the head and neck of the bone, and those parts, with a portion of the shaft, including the trochanters, were removed, the bone being cut across with a common saw. The patient bore the operation well; the previous bad symptoms soon disappeared, and in two months he was able to move about the wards of the hospital on crutches, the wound being nearly closed.

The paper concludes with a short historical sketch of the operation, whereby it is shown that this is the second instance in which it has been successfully performed in this country, having been first proposed by Mr. Charles White, of Manchester, in 1770, and first performed by Mr. Anthony White, of the Westminster Hospital, in 1818.

Additional Observations on Obstructions of the Pulmonary Arteries, By James Paget, Esq.

This paper is intended as an appendix to that on the same subject, communicated by the author last year, and published in the last volume of the transactions of the society.

A man fifty-five years old, was under treatment for stricture of the urethra. His general health was considered pretty good, and he made no complaint to his attendant of any thoracic disease, but, one afternoon, while, to all appearance, in his usual health, he fell on his face from his bed's side, and died in less than two minutes.

On a careful examination nothing was found that could have caused death, except the obstruction of nearly all the larger branches of the pulmonary arteries, by old and variously discolorized and altered clots of blood. In other parts, the blood was fluid, or soft and recently coagulated. The kidneys were slightly granular, but no other organ was importantly diseased.

The author discusses the cause of death, and of the coagulation of the blood in this and similar cases. He maintains, that in the cases which are not complicated with structural disease of the lungs, death is produced, not by asphyxia, but by gradual retardation, and at last cessation of the movement of the blood through the substance of the heart and brain, the systemic circulation becoming gradually slower, as more and more of the pulmonary arteries are obliterated, and less blood is transmitted through the lungs. Hence it is he thinks, that, in the majority of the recorded cases, though the disease was long in progress, yet the signs of danger and death were sudden.

The author alludes to several circumstances which he believes may cause an arrest of the blood in the pulmonary vessels, and its consequent coagulation; but he suggests that the chief one is some morbid state affecting its constitution, so as to increase that adhesion of it to the walls of the vessels, which constitutes even in the healthy state, the greatest resistance which the heart's power has to overcome. Such a diseased state he believes is produced by the existence of urea in the blood; and in confirmation of this opinion, he remarks that in at least three of the five cases in which no other cause could be assigned for the coagulation of the blood in the pulmonary arteries, the kidneys were granulated.

Case of Strangulated Hernia reduced en masse, *with Observations*. By Robert Wade, Esq., Senior Surgeon to the Westminster General Dispensary.

The patient, a man in his seventy-fifth year, who had been afflicted with inguinal hernia on both sides for nearly thirty years, was seized with the usual symptoms of strangulation. On examination no appearance of hernia could be detected. Purgatives and enemata failed in procuring evacuations. The circumstance of a slight darting pain having been experienced by the patient in the right inguinal region, on getting out of bed on the day that he was taken ill, and that on coughing the hernia descended on the left side, but could not be made to protrude on the right, led to the conclusion, that the right hernia, with its investing sac, had been reduced *en masse* by the patient, and that the obstruction existed in the neck of the sac on that side. The author accordingly operated on the right side, in the evening of the second day. The inguinal canal having been freely laid open by a division of the tendon of the external oblique muscle, the sac, which was much thickened and closely embraced the intestine, was opened. It contained a small knuckle of congested intestine. A membranous band, distant as far as the finger could reach, was divided, and the strangulated intestine was then reduced. The patient afterwards recovered.

The author concludes the paper with a brief notice of twenty similar cases, recorded by British and Foreign surgeons, and remarks, that a consideration of these cases cannot fail to suggest the necessity of the most careful examination being made in every instance where symptoms of internal strangulation are present.

Account of two Cases of Aneurism in which there was neither pulsation nor abnormal sound. By T. A. Barker, M.D., Physician to St. Thomas Hospital.

In the first of these cases there was a large aneurism of the aorta, commencing about two inches above the heart, and extending a little beyond the origin of the left subclavian; through the whole of which space the artery was at least three times its natural diameter.

In the second case there was an aneurism of the right renal artery, of the size and shape of a heart of ordinary bulk.

In the first case the aneurism was not detected during life; and, in the second, it was discovered only the day before death; although a *post mortem* examination did not reveal any cause of the absence of the ordinary symptoms.

The cases are considered remarkable not because large aneurisms existed without being detected; but because neither pulsation could be felt, nor abnormal sound heard, although certain symptoms had led to the strong belief that aneurisms existed in the arteries where they were afterwards found; and repeated and careful examinations were made with the expectation that unequivocal symptoms of aneurism would be detected.

Observations on Fissure of the Palate. By Alexander Nasmyth, Esq.

The interesting paper lately laid before the Society by Mr. Fergusson "on the Anatomy, Physiology, and Surgical Treatment of Fissure of the Palate," has induced the author to submit his views on the Mechanical Assistance which may be offered in cases where such surgical treatment may be unadvisable or not submitted to.

The author corroborates from his experience the accuracy of Mr. Fergusson's statement, that of late years English surgeons, generally, have abandoned cases of fissure of the palate, and left their patients to apply for mechanical adaptations. After applauding the superiority of a formation or restoration of the parts to a natural state over every other kind of assistance from art, and admiring the important step towards the improvement of the purely surgical operation made by Mr. Fergusson, the author takes a review of the mechanical contrivances which have been had recourse to, both in this country and abroad, distinguishing between those for congenital fissure, and those for fissure arising from disease. He shows wherein those contrivances have been found to fail—states the inconveniences inseparable from mechanical adaptations, also those consequent on the surgical treatment—describes the nature of the cases which indicates the propriety of mechanical interference, and those which forbid such interference—simplicity and durability being the great desiderata sought to be obtained in these adaptations. He also describes the contrivances by which he has attempted to arrive at those ends, explaining what may be reasonably expected from following out his views; and he shews that, in cases of fissure arising from disease, perfect deglutition and articulation may be confidently promised: that in congenital cases deglutition may be perfectly established, and very great aid afforded to articulation; and that articulation in congenital cases particularly requires time and perseverance on the part of the patient, great care and exactitude on the part of the practitioner, but that those requisites secured, great benefit may always be promised, if not distinct and perfect articulation anticipated.

Statistics of Bethlem Hospital, with Remarks on Insanity. Part II. By John Webster, M.D., F.R.S., &c.

After referring to his previous paper, published in the 26th vol. of the Society's Transactions, the author makes some remarks respecting the period of the year, when mental diseases were most prevalent, when the greatest number of patients were cured, and when the largest proportion of deaths occurred at Bethlem Hospital. These points he illustrates by a table compiled from the official registers (which shows, that most lunatics were admitted into the institution during the second and third quarters of the last twenty-two years, most were cured during the third and fourth quarters, whilst the largest number of deaths were met with in the last, but especially in the first quarter of the above series of years). The author next alludes to the occupation of insane patients, and states, that sixty-six per cent. of the inmates of Bethlem Hospital are now employed. This employment of the insane is found to have a very beneficial influence in their treatment, and tends materially to diminish the necessity of using personal coercion in the management of lunatics; in proof of which, the author states, that five years ago, the weekly average of persons under restraint was thirteen, whereas at present, when the system of employing the insane patients is more developed than formerly, during

some weeks, only one, and occasionally, not even one individual is in restraint. The author subsequently gives a synopsis of twenty-eight autopsies recently performed at Bethlem Hospital by Mr. Lawrence, thus making 100 *post-mortem* examinations of lunatics, if the seventy-two dissections previously reported are taken into the account. The diseased alterations of structure are succinctly described in the twenty-eight cases now brought before the Society, of which the following may be given as a summary. In twenty-five, there was infiltration of the pia mater. In twenty-four, turgidity of the blood-vessels. In nineteen, effusion into the ventricles. In twelve, fluid was found at the base of the brain; besides other varieties of morbid appearances. In twenty-two cases, the organs of the chest were diseased; and in thirteen, the abdominal viscera were more or less affected. In conclusion, the author makes some general observations on the facts contained in his paper.

THE FATAL RESULTS OF OPERATIONS

(To the Editor of the Medical Times.)

SIR,—Being much struck with the judicious observations you have made on the fatal results on the great proportion of surgical operations, and of the unpardonable desire *pure* surgeons have to perform them, I am prompted to subjoin an extract from the works of the celebrated John Bell, to which my attention was directed on a late occasion by Mr. Lawrence, and I am fully persuaded that the present is above all others, a most favourable opportunity to draw the attention of the profession to this point, the more especially as it is at this moment deeply interesting to the community.

I myself am one of those old-fashioned practitioners who have long thought that these *pure* surgeons, as they ironically style themselves, ought to be responsible in a court of justice for their wholesale dealings with human life, for surely it is no apology after killing a man with a scalpel, to say that its application was the *only* chance of saving him, when every man of common sense and experience would avow that there was *no* chance.

HUMANITAS.

"The passion of acquiring character in operations is surely full of danger. It is fit for those only to profess, who have no higher claim to public esteem. * * Those qualities which relate to operations and other public exhibitions of skill are of a very doubtful kind, while the duties of humanity and diligence are far more to be prized; they are both more amiable and more useful." Again. "That affectation of dexterity, or doing operations quickly is a pitiful ambition in those who use it; but you will invariably observe, that none except those who are deficient in moral courage, either find it requisite or think it necessary to resort to such conduct; and that a man who feels himself equal to the task he undertakes, proceeds deliberately and calmly, steadily bearing in mind the great object—relief to the patient." *Discourses on Surgery, by John Bell.*

NEW COLLEGE OF GENERAL PRACTITIONERS.

To the Editor of the Medical Times.

SIR,—Had a single argument been wanting to establish the imperative necessity for an *independent* College of General Practitioners, the recent memorial of the College of Physicians to Sir Jas. Graham, which you published in your valuable journal last week, furnishes it.

It likewise supplies strong, and with other data, irresistible arguments for sweeping away the proposed measure of a preliminary board and making in its stead the College of General Practitioners THE portal by which every future member of the profession should enter.

Thus, Sir James Graham's plan would be simplified, while one of his leading objects, that of having only one mode of ingress into the Profession, would be retained, and to each member would be ensured a comprehensive acquaintance with the various branches of professional knowledge.

Let our New College be an independent one, based on a representative organization, having from self interest illustrious names among its examiners, and a complete curriculum of education. Let each candidate undergo a thorough examination, and he will then enter on his profession, stamped with competency to its varied requirements, and a healthy impulse will be given to the whole medical body.

For my own part, when I consider all these circumstances, and others equally weighty, I come to the conclusion that the best title for the new College would be "The Royal College of Surgeon-Apothecaries," and that, for *each member, Surgeon-Apothecary.*

Under the *new auspices*, annexing the title Apothecary to that of Surgeon would cease to be in the least degree derogatory.

The public, more especially the provincial public, would understand these terms infinitely better than the long roundabout titles at present proposed, and they would also be more available.

In the country at least, the term General Practitioner would require a century to give it currency with all classes of the community.

Moreover the College of Physicians and the College of Surgeons would each be deprived of their present grounds of objection to the title of our Institution.

As for the College of Physicians being entrusted with the *medical examination*, and the College of Surgeons with the surgical examination of candidates for the diploma of the new college—such a proposition cannot for one moment be admitted; it would indeed *well suit their* purpose, that they might send men as examiners whose names could confer no lustre and lend no weight; it would *well suit their purpose*, that they might keep their new and vigorous rival fettered, hand-cuffed, stamped with inferiority and *dependent*.

Sir James Graham deserves high praise for patient and pains-taking attention to the cause of Medical Reform, and he will not we confidently hope, disappoint our expectations that our interests will be amply secured.

We *long* for the bill to be passed in a way that will satisfy us, and if it does, we shall be ever grateful to Sir James for sweeping away the Augean difficulties, which have so long obstructed Medical reform, and which so loudly proclaim its necessity.

I have the honour to be Sir,
Your humble Servant,
A qualified Surgeon & Apothecary,
of 12 years standing.

STATEMENT OF THE COLLEGE COUNCIL.

To the Editor of the Medical Times.

SIR,—I send you the following digest of the recent "statement" of the Council of the College of Surgeons, for the use of such of your readers as do not feel inclined to read and reflect on the original article:—

Paragraph 1. Assures us that they (the Council) are the guardians of the Surgical Profession. How well they have discharged their trust, let the old Members and the new Charter tell.

2. Lets out the secret, if secret it could be called, that Sir J. Graham's primitive Physic and Surgery Bill, and the College Charter, were one and indivisible—a wheel within a wheel.

3. Laments that Sir J. Graham is at length aware of the deep designs of the Council, and will no longer aid and abet in carrying out their avaricious and exclusive policy. And this, they say, is a sad breach of faith; no doubt *they* do; but their members are thankful for their narrow escape.

4. Lets loose the dogs of war. The Council cannot conceive what right such degraded and ignorant wretches as General Practitioners, who charge the public no more than they can afford to pay, have no "free days," and supply their own medicines, instead of sending their prescriptions to druggists on the *per centage* system, can have to a charter or college; and assures us, that notwithstanding their own certificates to the contrary, such practitioners can be no more than Apothecaries, and will make very bad Fellows of any institution.

5. The Council do not know exactly what to think; but have a strong suspicion that they and their Fellows are likely to come off "second best" in fair competition with the General Practitioners.

6. Makes it appear that the Council are ignorant of the nature of the preliminary examination, and consider that it is to be of a professional nature, medical and surgical. Perhaps we are no better informed; but a general opinion prevails, that it is to be merely classical, and would be much better performed by twelve schoolmasters. The same system has always obtained at the Hall and College of Physicians, and it is only the College of Surgeons that has hitherto required that its Fellows and members should exhibit no human knowledge beyond surgery and anatomy.

7. Expresses well-grounded fears that no Fellow of the College of General Practitioners will think it worth his while to become a member or Fellow of the College of Surgeons: and this, they say, will take a great deal of grist from their mill.

8. Is comprised in this extract: "It will not escape notice, that the proposed Corporation, in *assuming* the name of a *College*, has no *legitimate* claim to a title, *properly* used to designate any institution of which the essential object is the *promotion of science and learning*." Heaven preserve us! that we should ever have lived to lay claim to the title of learned and scientific men!

9. Graciously grants permission, that if the General Practitioners are not pleased with the present Apothecaries' Hall, they are at liberty to establish another.

10. Tells us what we too well knew before, that such of their members as, twenty or forty years ago, went through the highest routine of studies, passed the highest examination, paid the highest fees, and obtained the highest honours, it was then in the power of the College to ask or bestow; and who were then examined by such surgeons as Cline, Cooper, Abernethy, Blizard, and Home, are now at liberty to acquire a *higher honour* by submitting to an examination by their fellow-students Brodie, Lawrence, Stanley, and Co., who have some doubts whether their masters were capable of examining. And this not gratuitously and for the honour of their profession, but for a further fee of *ten guineas*.

The document concludes as it began; the Council lauding themselves for the *faithful* discharge of their duties; not having the fear of their last manifesto before their eyes, in which they branded themselves with the infamy of having taken money from their members under false pretences, by giving them examinations that were a farce, and certificates that were a fallacy.

I am, Sir, your obedient servant,
June 24, 1845. F. D. B.

GOSSIP AND NEWS OF THE WEEK.

A Sign of the Times.—The Sheffield Medical Book Society at their meeting on Saturday, 28th June, unanimously decided to reject the *Provincial Medical and Surgical Journal* from their list of periodicals. This occurring on the eve of the visit of the Provincial Association to this town, is not a little ominous. (Authenticated to us by a respectable medical resident.)

Amos Jowett was admitted a licentiate of Apothecaries' Hall on the 28th of June, 1845.

The following gentlemen were, on the nomination of the Board of Censors, selected last week from the list of Licentiates, and received the honour of the Fellowship of the College of Physicians:—Dr. Jenks, of Brighton, Dr. J. Latham, Dr. Golding Bird, Dr. Bence Jones, Dr. Seth Thomson, Dr. Pereira, Dr. Pittman, and Dr. Patrick Black. Considering the reputation and talents of the gentlemen promoted, the selection does not do the College much honour.

COURSE OF LECTURES ON THE THEORY AND PRACTICE OF MEDICINE.

Delivered by C. J. B. WILLIAMS, M.D., F.R.S., Professor of the Practice of Medicine, and of Clinical Medicine at University College.

We now come to the diagnosis of intermittent fever. The symptoms are of a marked character, and the accession of the fever occurs towards the evening or towards the morning. The accessions are accompanied by disorder of the urinary organs, as in the cold stage of ague, but there are other symptoms of fever; dryness of the tongue, and thirst; headache, rigors, and pains in the loins, and in some cases there is delirium. These are some of the symptoms of the cold stage. They are followed by the hot stage, in which the patient is oppressed with heat; the pulse is hard and full, and the headache continues. Then comes the sweating stage, in which the perspiration is extremely profuse, and affords the patient considerable relief.

The causes of intermittent fever are various circumstances which weaken the system; poor living, irregularity of diet, mental anxiety, and more particularly cold, but not extreme cold. These may excite the disease where it has previously existed. Many who have suffered from a severe fever, feel something of an accession of ague, whenever the wind blows from the East, or whenever they take cold. The exciting cause of intermittent fever is mainly if not exclusively malarious poison, which arises from stagnant water, marshes, and damp clay soils. It occurs most commonly in the spring and autumn, but often prevails throughout the summer. There are two points to be explained in the nature of intermittent fever:—one is the character of the series of phenomena that occur,—what it is—on what does it depend? the second, the reason why these series of phenomena occur periodically at such stated periods. Cullen supposed that the malarious influence which was the exciting cause of the fever, was at first sedative to the nervous system, accompanied by spasm of the extreme vessels, creating the cold stage, and the re-action caused thereby in the heart and arteries, led to the hot, and subsequently to the sweating stage. The assumption of spasm of the extreme vessels is altogether gratuitous, for there is nothing whatever to cause any such spasm in inflammation or fever. With regard to the second point, Cullen ascribed the periodicity of the fever to the general law of the animal economy, as exhibited in the diurnal returns of sleeping and waking; that is a tendency to the periodical recurrence of the phenomena, and the diurnal returns of the appetite and the secretions. This periodicity is observed to a great extent in many other diseases, and many other fevers. This view has been adopted by other writers without acknowledgment; Broussais and others have applied it to gastro-enteritis, but he does not explain why that disease is peculiarly intermittent, but only adduces other cases in which there are intermittent inflammations, and likewise the fact that inflammation of the enteric mucous membrane is one of an intermittent kind. It is true that we find many diseases to be intermittent, but it is *in* malarious districts that they become so, and under these circumstances a sort of febrile paroxysm is produced. Now if you take into consideration the mode in which these things act, you will arrive at an explanation of the general law of the periodicity of the attacks, as well as of the mode in which they occur. I have mentioned that the earliest effects of malarious poisons are sedative and depressing, injuring the bodily powers, oppressing them, and more particularly affecting the capillary circulation, and the secretions: whether it does so affect the capillary circulation and secretions, by an influence exerted through the nerves, or through the blood itself, by changing its quality, we do not know: this is not made out. But we see that the constant result of the operation of this causes the great changes produced in the capillary system. We find that the essential operation of malarious poisons is to produce great external constriction and great internal congestion. The blood accumulates from some cause or other in the internal organs to a great extent, before the fit actually occurs, sometimes for a series of days without any reactive power, and when the congestion reaches a particular degree, then the re-action occurs, which terminates in the hot stage. But before you come to the cold state, you will see the manner in which malaria will operate, and the manner in which sometimes its bad effects will be thrown off. Sometimes some secretion will take place; diarrhœa will occur, and then lymph is thrown out, and the person does not suffer from ague. So, too, under the slow influence of the poison, the person suffers not from cold, but from some internal disorder, such as hepatic congestion. Sometimes where there is a predisposition to a rheumatic attack, or epilepsy, or asthma, all these are effects created by the malarious poison before the fit is determined. But if it goes on to a greater degree in persons without these predispositions, the cold fit is actually produced; the bodily powers seem momentarily quite oppressed by the influence of the poison, and when internal congestion reaches the greatest degree, re-action begins, and convulsion, affecting the nervous centres. Shivering, which is only a slight convulsion, takes place; the other parts of the excito-motory system are called into action, and vomiting, and more or less difficulty in breathing ensue. As the re-action increases, the circulation becomes more hurried, the blood flowing more and more to the surface, and thus the hot stage is developed, which continues until by exhaustion of the powers the crisis takes place; perspiration, and abundant urinary deposits; free secretion from the alimentary canal; and then the symptoms subside: the morbid matter has ceased for a time to operate, the balance is restored, and the patient, except being weak, is in a state of comparative health. But the morbid poison is still in the system, and begins to operate sooner or later. In proportion as the bodily powers are strong, the longer do they resist the disorder, and the intermission may be more complicated. When the fit does recur, the re-action may be more energetic, and by its energy throw off the poison and its effects for a longer period. On the other hand, if the bodily powers are weak, and there are symptoms of constant disorder, the poison keeps up this disorder, and the patient is continually ill. This is what we find in different inflammatory fevers. Another effect of this continuance of the action of the poison where the patient is weak, or the poison strong, is that there will be not only distinct febrile paroxysms produced, but the structures will be ultimately affected; the congestion continuing in the intervals of the fits, there will be the consequences of those congestions which I have many times pointed out under the various changes of structure. It is under these circumstances that the chronic form of ague takes place, and diseases of the liver and spleen, and various other disorders of the viscera occur. On the other hand, if the disease is of more recent occurrence, instead of hypertrophy, the congestion may lead to the production of inflammation, and in this case the ague is complicated with inflammatory diseases, and it is in this case sub-intrant ague, which is nothing more than the congestions producing ague being re-acted on. This takes place mostly in persons of a sanguine temperament, and in whom irritations or causes of irritation exist; as, for instance, under the influence of cold, the mode of diet, &c. Under these circumstances, the congestions become inflammatory, and gastritis, hepatitis, pneumonia, and so forth, may be the result. There are changes produced by malarious poison, besides paroxysmal changes, and persons in malarious districts, who are accustomed to the operation of the poison, are more liable to attacks of ague, than they are to the continued effects of the poison, internal congestions leading to structural changes of different kinds. There are many affections which may be mentioned, such as rheumatism, neuralgia, gout, headache, asthma, dyspepsia, paralysis, and many other forms of disease which may be excited by the action of malarious poison. A great many of these are connected with internal congestion, and may arise from inflammation, and more particularly from an impaired state of the secretions. Dr. Prout holds the opinion that malarious poisons so far change the chemistry of the body as to produce changes in the texture; but this is merely hypothesis. These effects take place in different ways in different subjects, produced chiefly in parts previously weak, and it is observed that persons who live in a malarious country, and who escape ague, die at an advanced age of the various visceral affections I have before adverted to.

The great indications in the treatment, are, to counteract the sedative influence of the poison; to get it out of the system, and likewise to remove its effects, and any morbid effects arising from reaction. As the strength of the poison varies, and as the amount of the reaction varies in different cases, the treatment must also vary much in different cases. The treatment must be divided into that connected with the paroxysm itself, and that connected with the prevention of its recurrence. With regard to the paroxysm, it may be considered as a struggle between the vital powers of the body and the malarious poison, and the vital powers are therefore to be exalted in the first instance, but afterwards they will require to be moderated. Hence in the cold stage, which is the time when the vital powers are lowest, and beginning to react, the re-action may be promoted by heat and

stimulant diaphoretics; a warm bath with stimulant medicine, and, owing to the predominance of nervous irritation, narcotics are often of use. Narcotics and stimulants together are generally the medicines for ague in the cold stage; a mixture of laudanum and ether—half a drachm of laudanum to a drachm of ether—should be given at the commencement of the cold stage. As soon as the re-action begins, the treatment is to be that called refrigerant, to promote the determination of blood to the surface. Various saline medicines that act on the secretions, and increase the secretions from the skin may be given, combined with antimonial medicines, the operation of which is directly on the arterial system. This is the chief treatment in the hot and sweating stages, together with measures to increase the secretions of the alimentary canal. Where the re-action is accompanied by plethora, it may be useful to draw blood, the more so if there are symptoms of local inflammation. In the sweating stage little need be done further than mild stimulating treatment. It may be necessary to accelerate the occurrence of re-action, by emetics given at the commencement; sometimes a fit of vomiting occurs spontaneously, which appears to have a similar action. Other means have been found likewise to stop the fit or to modify it considerably. The application of ligatures or a tourniquet to the large arteries, has in many instances accelerated the re-action. The pressure should be kept up for two or three minutes. It operates by directing the force of the circulation from the internal parts, and removes the congestions that have already formed, but its great efficacy is in the cold stage when the circulation is most depressed. The same thing has been done by blood-letting in the cold stage, certainly with some relief, but it is very absurd, practically speaking, to produce a temporary advantage at the actual expense of the blood. We know that blood is wanted to sustain the system under the continued effect of the disease. In the intervals, the great object is to remove any remains of congestion or inflammation left by the fits, or by the influence of the poison, and likewise to act on the secretions continually. There are various measures to remove the congestions, and the tendency to that state. Emetics, and active mercurial purgatives are very powerful means of removing internal congestions, and are to be given in proportion to the amount of the congestion. If there is hepatic congestion, it will be necessary to use mercurial purgatives, with leeches or cupping; if pectoral congestion, bordering on inflammation, then it may be necessary to use blood-letting. As soon as the congestion, and tendency to inflammation are removed, the great object is to increase the tone of the vascular system by the use of tonics. The great effect of tonics is to improve the tone of the vascular system, and to prevent the effects which directly arise from the poison. This is the great reason why intermittent fever is so much more tractable than any other. There is a period in which the re-action does not exist, and in which there is in most cases no material complication to interfere with the exhibition of tonics, which may be given most freely. This is not the case with regard to continued fever. Bark and its preparations, and arsenic are the chief medicines to be given in these cases, and they are to be given in as large doses as the stomach can bear, care having been taken previously to remove any considerable congestion existing in the abdomen, and care is necessary in the exhibition of bark and quinine, that there be no complications of fever, and that the fever itself shall have been subdued for the time. They may be given on the termination of the sweating stage in doses of three grains up to a scruple, every three or four hours in the intervals. In gastric affections, where there is no inflammation, the preparations of bark may be given, but they should be combined with mercurial purgatives, otherwise they may prove too stimulating to the alimentary canal. The presence of mere congestion in the liver and other parts, without signs of irritation, is no counter-indication to the use of tonics; and it is remarkable how, where there is no inflammation, it has an influence on the tonic property of the vessels themselves. If the various viscera be not only congested, but there are some signs of inflammatory action present, and the secretions are much involved, then it may be necessary to use measures to increase the secretions by preparations of mercury, and where there is inflammatory action, the less stimulant and anti-periodic medicines may be used; arsenic in doses of six minims increased up to twelve, every four hours, and if there is nausea or griping, tincture of henbane, or tincture of opium may be useful. The sulphate of zinc, or the hydrophosphate of ammonia has been given with some effect. Diseases connected with these congestions are often curable by the antiperiodic treatment, but it is of great consequence in all these cases to see that the secretions are kept free; mercurial medicines are useful for this purpose in intermittent fevers. It is of great consequence to remove the patient from the malarious district, and if this is not done there is less chance of a speedy cure. It is of great importance for persons inhabiting malarious districts to avoid exposure to the wind blowing from the marshes, particularly in the evening and morning. The apartments should be kept warm but well ventilated. Persons should avoid going abroad when they are predisposed to receive the poison, and they should also avoid exposure to malaria on an empty stomach, and they should live well and regularly, and be well clothed. If any deviation from the general health should be observed in persons living in malarious districts, the secretions must be kept free, and quinine may be given.

LECTURES ON DISEASES OF THE HEART.

By D. J. Corrigan, M.D., Physician to the Whitworth, Hardwicke and Richmond Hospital, Lecturer in the Dublin School of Medicine, &c.

PERICARDITIS.

We come this evening to the consideration of pericarditis, or inflammation of the sero-fibrous membrane investing the heart. We shall first consider its pathology, then its diagnosis, and finally its mode of treatment.

The pericardium is a sac of the sero-fibrous class of tissues investing the heart, its office being to secrete a fluid called liquor pericardii, which lubricates the heart, and allows it to play freely within the pericardium. Pericarditis may exist uncombined with any other disease, or it may be complicated with pneumonia, pleuro-pneumonia, endo-carditis, or valvular disease of the heart. Looking at the pericardium in the dissecting room, you could not imagine that it possesses such power of distension as pathology discovers to us. This membrane is identical in structure with the pleura, and inflammation of it may terminate in any of the ways in which pleuritis does. Thus, we may have in pericarditis, effusion of serum with coagulable lymph thrown out on the surface of the heart and pericardium, or effusion of serum and pus; or lastly, a variety of effusion which has been termed hæmorrhagic: the name clearly explains its nature. When coagulable lymph is effused on the surface of the heart and pericardium, it becomes in some cases organized; fibrous bands shoot across, connecting one with the other, which when ruptured give the heart a peculiar granulated appearance, which from its resemblance to the outside of a pine-apple, has procured for the organ in this state the name of the "pine-apple heart."

In these jars are some preparations illustrating this form of heart disease, but such things soon spoil, being acted upon by the spirit, and eventually are unfit for their primary purpose: that of illustrating the changes produced in parts by disease.

Inflammation of the pericardium may prove *immediately* fatal, or death may ensue within twenty-four or forty-eight hours after its accession, or life may be prolonged under it for a period of six weeks, as happened in the case from which this cast has been taken; or the disease may run on between three and four months, as happened in a case which proved fatal about twelve or fourteen months ago at the Hardwicke Hospital. I mention these facts to disabuse your minds of errors with which they may be imbued, by placing confidence in the assertions laid down in books, where this disease is said to be very quickly fatal. I mention them, that disregarding all ideas of the sort, and throwing aside pre-conceived opinions, which would lead you to believe, that because this disease may have existed for a certain time, your efforts at relieving it must prove futile, you may be led to employ the efforts of art, and perhaps successfully too, for the relief of this disease: a disease which, no matter what books may say to the contrary, I have found from experience to possess as great a claim to the character of chronicity as many other diseases commonly so regarded. I think that a disease wherein we may employ our remedial measures for three or four months, may well be called chronic.

When the termination of inflammation is by the effusion of sero-purulent fluid, or serum, the pericardium sometimes acquires an enormous bulk. Here, in this cast (showing one on the table) you see it rising completely up to the *fourchette* of the sternum, pressing upon, and causing œdoma of, the lung at that side. In the case which I spoke of, as having proved fatal within the last fortnight, the effusion was fully twice as great as in this cast. In other cases which prove fatal, the effusion is sometimes but small in quantity. In cases where the fluid rises high in the chest, bronchial respiration is heard in the portion of lung above its level. It is easy to understand why the fluid in the pericardium, or rather the distended sac itself, should rise high in the chest, as the sac can be distended only in two directions; either directly upward, as in this cast where it has risen as high as the sterno-clavicular articulation, or to the right side, which you perceive also distended in this cast. Downwards it cannot descend, owing to the resistance given it by the tendinous portion of the diaphragm; and it cannot go backward owing to the situation of the heart.

Now for its symptoms and diagnosis: pericarditis may arise from exposure to cold, or from any other of the many causes of common inflammation; and it frequently arises where no cause whatever can be assigned for its origin. It is very frequently produced by over-exertion in young persons—recruits on march, for instance, who, unused to severe walking, attempt to keep pace with veteran soldiers, particularly if to this over-exertion is superadded the depressing effect of hunger. But the form of the disease which has attracted most the attention of physicians, is where it arises during the existence of rheumatism, whether as metastatic, or merely as an accessional item to swell the list of the organs previously implicated.

While on this topic, I may as well here, even at the risk of digressing from the immediate subject of the lecture, make a few observations on some points connected with rheumatism, these also having a bearing on the subject. We may naturally ask ourselves, why in rheumatism affecting the joints (fibro-serous structures equally as the pericardium) we seldom or never find effusion taking place into their cavities, while in pericarditis it is such a general result? I think that the question admits of a very easy answer. We must recollect that in rheumatic inflammation of a joint, we have a specific cause of disease existing; this may also exist in inflammation of the envelope of the heart: but if to this specific cause we also add the common one of inflammation, if while the joint is labouring under specific inflammation, we make the patient take active exercise, what is the consequence? Lymphy inflammation is excited from both causes, and fluid is effused within the joint, or the inflammation may reach to such a height, as to cause ulcerative absorption of the cartilages, and finally of the bones themselves composing the articulation. This state of things exists in the heart; no matter what intensity or form of inflammation may exist upon itself or upon its lining membrane, it must do its work ceaselessly. This of course adds to the existing inflammation, while in cases of rheumatism of the joints, instinct forces the patient to have recourse to the utmost quietude, and consequently we seldom or never find effusion as a sequel of inflammatory action produced within their cavities.

It is a very common opinion, that rheumatic pericarditis never takes place but as a metastatic

disease. This opinion, if you believe it, will be productive of the most prejudicial practical results; nothing can be more erroneous than this idea. The rheumatic inflammation may be disappearing from the extremities, when your patient may be seized with pericarditis, or the rheumatism may attack the joints with the utmost severity, and you may not have it present; but bear in mind, that pericarditis may exist and proceed, *pari passu*, with the most intense form of articular rheumatism.

Pericarditis may be advantageously divided into three stages, every one of them possessing marks peculiar to, and characteristic of, itself; and when called on hereafter to treat the disease, you will find them of very great importance in regard to its treatment. Previously to entering upon the diagnosis of pericarditis, I would wish to call your attention to a very important fact, and as a preface to the remarks I am about to make, I shall take the liberty of using Bichat's beautiful and eloquent language on a similar occasion to his class. "Why," he says, "trust to books for information when the great volume of nature is opened before you? Why trust to copies while you possess the originals? As well might a painter, anxious to arrive at excellence in his art, trust to sorry and imperfect prints of the works of the great masters, when the glorious originals are before him, inviting his attention." In like manner I say to you, why trust to sorry representations of disease, when the originals invite your attention? Why trust to books, to I may say the almost total exclusion of hospital practice? Far better would it be for your own practical information's sake, and for the future welfare of your patients, if the hours which you now devote fruitlessly, though with the best intentions on your part, to the history of diseases as laid down in books, were spent in a hospital, at the bedside of a patient, there delineating from nature, every, the most minute trait in the picture of disease, thereby acquiring an amount of information so extensive and accurate, that years of book-learning could not make you possessed of its equal. I have been led to make these observations by the absurdities which surround the history of disease in works which come into your hands as class-books. Turn to any Cyclopædia of Medicine—Copland's for instance—to the article Pericarditis, and what information does it give you on this head? It tells you that the action of the heart may be frequent or slow, regular, irregular, or laborious, strong or weak, and that the pulse may be hard or soft, regular or irregular, quick or slow, full and bounding, or soft and compressible, strong or weak. In fine, after reading the article in question, you rise from its perusal with your ideas of the disease as much in the dark as ever, while any information about it which you might have previously possessed, is mystified by the incongruous train of symptoms which may attend upon it. Now, to what is this owing? To the following fact, that the majority of works on the practice of medicine are, I shall not say written, but compiled by men who know but very little of the diseases which they pretend to teach the knowledge of to others. We must suppose that they know something, however, of the disease, and even this trifling knowledge though it be, would be of service to the student, if properly communicated; but, the hurry and confusion of publishing a work puts them so much beside themselves, that from such a work the student in vain attempts to glean correct information. A fact, illustrating what I have just now stated, has lately come within my own knowledge. For a medical work, published some time ago (and which, I am sure, is often in your hands,—its name I am not going to mention), two or three persons in this city were applied to, to write the articles on diseases of the heart. Whether it was that pressure of business prevented the gentlemen applied to from doing so, or that the publishers of the work conceived they *could get the job done* at a cheaper rate by others, certain it is, that the persons first applied to never penned the articles in question. In consequence of which they were written by a person who, I am confident, in the whole course of his professional life, never had under his care a single person affected with heart disease; and, I am equally sure, that in his hospital practice he never watched the progress of half a dozen such. Is it to be wondered at then, that from medical compilations the student should glean anything but information concerning diseases, and knowing this, is it at all strange that I should impress upon you the necessity of reading for yourselves from the great book of nature, and throwing systematic books, in a great measure, overboard? To be sure, you must read something, but I think that in the practice of physic and surgery, hospital observation and clinical instruction are the best means of acquiring a knowledge of disease in all its phases.

I shall now proceed to lay before you the symptoms of pericarditis in its different stages, faithfully drawn from observation, commencing with the first stage, which we will suppose to have set in with a person labouring under rheumatism. You go to him in the morning, you find his rheumatism getting better, and that he is, in every respect, much improved; you examine the heart, and you find it natural. Your patient has been taken worse suddenly in the evening, or perhaps in the middle of the night; you are sent for; what appearance does he now present? The countenance puts on an expression of the most intense anxiety, the alæ nasi are dilated, the respiration is hurried, and irregular, as in persons who have suddenly met with a great shock, the lips livid, the skin cool, or cold, and perhaps bedewed with perspiration, the pulse weak, thready, and small, while on examining the heart, you find it beating tumultuously, and irregularly, as if every fibre of it were contracting one upon the other. This state of things may continue for an uncertain period of time, three, six, twelve, or twenty-four hours; if your patient survives for twenty-four hours, he is safe from the first stage. During the continuance of this, it has not unfrequently happened that patients, on making the trifling exertion of getting up in bed, have fallen into a syncope, which has proved immediately fatal, thus giving rise to sudden death, while labouring under acute rheumatism.

Let us examine what it is that takes place here, or if a knowledge of what produces this train of symptoms can have any bearing on the treatment of the disease. Nature, at the onset of this affection, is labouring under the depressing influence of the sudden shock produced on the constitution, by the attack of inflammation in an organ of such vital importance as the heart. All the symptoms which I have detailed as characterising the first stage, are so many evidences that the constitution has suffered a grievous injury. Look to what takes place when a person meets a severe local injury: have we not exactly the same symptoms of shock, differing, it is true, in intensity, on account of the less important character of the part affected? Do we not find this shock take place on the accession of fever, or inflammation of any organ or part? For the rigors which usher in these last affections are still of the same nature as the terrible train of symptoms which ushers in pericarditis. We shall presently find that a knowledge of this fact will prove very advantageous in our treatment. This stage having lasted three, six, twelve, or twenty-four hours, as the case may be, the second stage sets in. The cheeks regain their wonted colour, and, perhaps, become flushed; the pulse becomes, perhaps, full and bounding. In this disease you can place no reliance whatever upon the pulse as an index to guide you in your treatment. The action of the heart is now felt strong and tempestuous; the stage of shock has passed away, and has been succeeded by inflammation. At this period a curious symptom is observed; if you ask the patient where he complains of pain, he immediately refers its seat to the epigastric region. Pressure upwards upon the space under the xiphoid cartilage causes pain. This might lead you to the conclusion, that the disease present might be gastritis, complicated with hepatic inflammation.

In the third stage, when effusion has set in, then percussion becomes useful. It now becomes an object with us to ascertain whether the effusion be large or small in quantity, and what its character may be. Have we any means of ascertaining these points? We have; as also of determining the important point whether the effusion be the result of pleuritis, or whether the dulness of sound over the region affected be the result of pneumonic inflammation. In pericarditis, when the effusion rises high in the chest, as in this instance, the line of demarcation between healthy respiration and dulness of respiratory murmur is not very well marked; it is somewhat indistinct. The reason of this you may know from this cast, in which the fluid contained in the pericardium has insinuated itself under one of the lobes of the right lung, thereby rendering the seat of the fluid not exactly definible by the stethoscope. The thick part of the lobe which overlaps the fluid gives out a clear murmur; this, according as the lobe gets thinner and thinner, towards the edge, gradually becomes more and more faint, until it merges at length into complete loss of respiratory murmur. From pleuritic effusion it may be distinguished by the following character:—suppose the pleuritic effusion to have displaced the heart to the right side: if the patient lie upon his back, in such a case no appreciable change will be produced in the situation of the heart; it still is felt beating in its abnormal situation; while, if the effusion depend upon pericarditis, such a manœuvre, by causing the fluid to gravitate backward, will enable the heart to be heard beating in its usual situation, though somewhat more faintly in sound, owing to the bad conducting power of sound which the fluid surrounding it possesses. In this third stage we have another curious phenomenon; we have bronchial obstruction, in consequence of fluid being poured into the minute bronchial ramifications, by the pressure exerted upon them by the pericarditic effusion; this may even cause pneumonia. In all these cases we find the respiration oppressed, and the countenance all through presents the same expression of anxiety which strongly marks the onset of the disease. From pneumonia it may be distinguished with ease, by the negative characters which it presents: thus, we have not the pneumonic "rale crepitant," nor its peculiar viscid rust coloured expectoration, and also, we want the most generally decisive test of pulmonary inflammation—that which I have laid particular stress upon when lecturing on pneumonia, namely, the peculiar pungent sensation of heat conveyed to the hand of the physician by the skin of the patient.

A symptom exists in pericarditis, called "frottement," which might lead an inexperienced stethoscopist to suppose that he had heard "bruit de soufflet." The two sounds are somewhat similar, but the difference between both having been once pointed out, can never be forgotten. I shall first explain to you how *frottement* is produced in this disease, and afterwards make you acquainted with the distinction between it and "bruit de soufflet." When lymph is effused upon the internal opposing surfaces of the heart and pericardium, so as to render each surface rough, which had been previously smooth, this sound is produced in consequence of the two rough surfaces rubbing against one another at each motion of the heart. In any case when you are in doubt whether the sound you hear be "bruit de soufflet," place the patient leaning forward, so as to throw the fluid effusion to the front and lower part of the pericardium. This position is one frequently adopted by the patient himself, as being productive to him of greater ease than any other. If while in this position you examine the heart, and find the former irregular sound inaudible, you may conclude that it is *frottement* you have heard; place him again in a horizontal position, and it immediately becomes audible: whereas if the sound be "bruit de soufflet," no change of position which you may suggest can at all interfere with its production. It is easy to understand why a change of position should cause or remove the sound of *frottement*. When your patient leans forward, a layer of fluid is thrown between the heart and pericardium, which prevents their attrition, and when he lies on his back, this disappears from the front, and gravitates to the back part of the pericardium, between the fifth and sixth ribs, forming a collection of fluid at each side of the

heart. I have remarked before that pericarditis may co-exist with endo-carditis. This may exist as valvular disease of the heart, or in another form of which I shall have to speak hereafter. Of the co-existence of both diseases, we can have no positive proof, but if we hear "bruit de soufflet" steadily, when the fluid is being absorbed, and the patient advancing toward recovery, under these circumstances we may infer that organic disease of the heart exists. Though we may hear "bruit de soufflet" irregularly during the existence of pericarditis, yet we must not from this alone be led to think that organic disease of the heart exists. We have already seen, that irregular action of the organ will produce the sound in question: this is heard frequently in pericarditis where not the slightest trace of heart disease exists. It was not audible in the last case of mine, neither was it in the case from which this cast was taken.

LECTURES ON THE PHYSIOLOGY AND DISEASES OF THE BRAIN,

By J. Bouillaud, D.M.P., M.A.M.,

Member of the Chamber of Deputies, Professor of Clinical Medicine at the University of Paris, Knight of the Legion of Honor, Physician to the Hospital de la Charite, &c. &c.

Lecture IV.

Meningitis.—Definition.—The denominations of ataxic fever, cerebral fever, and arachnitis have been in turn given to this disease, for which I consider meningitis by far the most appropriate. It sometimes happens, it is true, that the arachnoid alone being affected, it may contain serosity and pus, or offer more or less numerous spots, covered by pseudo-membranes; but these cases are very uncommon, and in most of those hitherto recorded, it is very probable that the phlegmasia was not limited to the serous membrane; besides which, the principal, if not the exclusive, seat of the disease is in the cellular tissue subjacent to the arachnoid, or in the pia mater. As to the dura mater, it participates in the affection only after some length of time, and in consequence of its contiguity, since it is only in chronic cases that it is found to be thickened, degenerated, or covered with cartilaginous or osseous plates and finally, even the bones of the skull may present certain lesions.

Divisions.—Meningitis may be general or partial, and may affect, separately or simultaneously the membranes covering the upper part—those covering the base of the brain, or lining of the ventricles. Dr. Foville has described with particular attention the variety which affects the parietal surface of the meninges; it is, however, very seldom seen independently of the phlegmasia of the other portions of the membranes, and when it does exist it is generally produced by external violence —such as wounds or fractures of the upper part of the skull.

Pathology.—The lesions observed do not differ essentially from those of inflammation in general, presenting only some peculiarities owing to the structure and the functions of the affected tissues. The first or acute stage is characterized by redness, which may be carried all at once to such a degree as to resemble an effusion of blood in the interior or on the surface of the tissues, being, notwithstanding, more considerable under the arachnoid, and in the pia mater. In the generality of cases, these two membranes do not present mere arborescent spots, more or less numerous, but they are turgescent and tumefied. Now, the only symptoms wanting to characterize inflammation as described in a pathological point of view, are heat and pain, but as these are phenomena purely physiological, they cannot be perceived after death. When thus affected, the tissues lose their cohesion, so much so that the pia mater, the arachnoid, the choroid plexus, and the lining of the ventricles are excessively friable, and may be torn with the greatest facility. This is what has been designated under the generic term of ramollissement, and is entirely analogous in its mode of formation to the softening of the brain and of all parenchymatous organs. In this stage the membranes are sometimes covered with granulations; these, however, are met with in chronic meningitis, or in a peculiar form of the affection, which of late has specially occupied the attention of writers on this subject. I mean meningitis tuberculosa.

The surface of the arachnoid and the ventricles are merely lubricated in the normal condition by a serous fluid, but no liquid is accumulated in their cavities, and if any be found at the *post-mortem* examination, it was probably formed during the last struggles of departing life. A secretion ought never to be considered as the product of inflammation, except when the chemical properties of the serosity, or of the secretion are changed. Now in most cases, the cavity of the arachnoid, or that of the ventricles is found to be distended by a considerable quantity of serosity, somewhat less transparent than in the normal condition. This is the real transition from the healthy to the inflammatory state. These active dropsies form a "*protophlogosa*," if such an expression be admissible, out of which the least augmentation in the symptoms is sufficient to form a real phlegmasia.

The symptoms of this "*protophlogosa*" are the same as those of ordinary inflammation, and they differ only by the character of the secretion. Thus in the former the ventricles and the arachnoid are full of a serosity varying, as already stated, but very little from the normal serum; whereas in the latter the liquid is thicker, viscid, opake, generally infiltrated under the arachnoid, or between the layers of the pia mater, where it is found in a semi-concrete form like jelly. The arachnoid and the ventricular membranes seem to be infiltrated, and to owe their thickness, and their puffy condition to this substance, which often fills the ventricles and the cavity of the serous membrane. In the former, the fluid separates into two parts, the one liquid and limpid, the other flocculent, amorphous and pulpy. These remarks suffice to show that there is not a great difference in the mode of formation of the *two degrees* of the same affection, although in considering only the pathological lesions they appear to be so different. In fact, in one, the acute dropsy (*protophlogosa*) remains stationary, furnishing an abundant liquid, whose qualities never change unless the symptoms increase in intensity from the disease being converted into real inflammation; in the other (*phlegmasia*) the serosity is lactescent, generally thick, and readily changed into pseudo-membranes, which in most cases are organised and offer numerous reddish streaks indicating the formation of new vessels.

If the disease, instead—as is most frequent—of terminating fatally with rapidity, is prolonged from three to six weeks, the pseudo-membranes being perfectly organised, and forming a part, as it were, of the arachnoid, the inflammatory symptoms decrease in intensity, the fluid secreted is not so turbid, is thinner, more limpid, and more abundant, and presents the characters of the former; finally, hypertrophy succeeds the inflammation. Dr. Foville, in an article on meningitis, has described cases in which the false membrane lined the entire cavity of the arachnoid, so as to form, as it were, a new cavity, and I myself last year had an opportunity of studying a very remarkable case of this description. May it not be admitted that with the exception of the false membranes, many cases of hydrocephalus have no other origin than that just mentioned: for often very milky layers may be observed adherent to the internal surface of the serous membranes, as after dropsy. The disease, however, is not always limited to these lesions, as suppuration may succeed to the injection, thickening of the membranes and secretion which is produced in the first stage: in some instances I have found healthy phlegmonous pus covering the pia mater, and sometimes the internal surface of the cavity of the arachnoid, or of the ventricles; it is likewise frequently seen under the arachnoid between the layers of the pia mater. The spot it occupies may be ascertained by pressing lightly on the serous membrane, as it is thus made to change its position.

Besides the anatomical lesions just described, granulations often more or less organised, and real tubercles, may be observed, situated on the surface of the arachnoid, or in the interior of the pia mater; it must, however, be remembered that it is not in every case that they exist, but chiefly, and perhaps exclusively in persons of a lymphatic constitution, who are also frequently affected with tubercular peritonitis, pericarditis, or pleuritis. I do not coincide in opinion with the authors who consider that the tubercles precede, and are the cause of meningitis; on the contrary, I think that they are always preceded by the inflammation, and that if once developed, if the phlegmasia yields to nature or to an appropriate treatment, they may remain for years without producing any lesion, in the same way as the granulations consecutive to an intense and neglected endocarditis. Now what is the nature of these tubercles, or granulations, which it must be confessed have been studied too superficially, and which most authors attribute, without being able to explain why, to a peculiar affection, one *sui generis*, whose real cause they will not admit? This is one of the most vast and most important questions, with respect to pathogeny, that can be examined, since it tends to explain not only the nature of tubercles of the meninges, but likewise tubercles in general. I do not hesitate to assert in the most positive manner that those who consider tubercles to be of a peculiar nature, and who refuse to admit that there is any relation between inflammation and these productions, and are shocked at my opinion, are in error; as I think what I state to be effectually proved, nay more, that all who will take the trouble to study the disease with attention, will be of the same opinion. I therefore announce as an established fact—1° That inflammation, and inflammation alone, is the efficient cause of tubercular deposit. 2° That this inflammation has its seat in the lymphatic system, determining there the secretion of matter, *sui generis*, which constitutes the tubercular affection. This assertion is supported by the generally recognised and admitted fact, that tubercles chiefly affect individuals of a lymphatic constitution. It may, however, be argued that tubercles are developed idiopathically, and in a primitive manner, and in proof thereof the transmission of the tubercular disposition, from parent to child, as an hereditary legacy may be urged; to this I will reply, without the fear of being proved to be in error by accurate observers, that tubercles are never transmitted, but the temperament which renders the individual apt to contract the tubercular affection—the predisposing cause—that is to say the lymphatic constitution—is constantly transmitted; for it is well known how few exceptions there are relative to the hereditary transmission of a temperament. The same remarks are applicable to inflammatory diseases, and the various organic diseases which may follow them. These affections are the upanage of the sanguineous temperament, and certainly no one would dare assert that pneumonia, for instance, is hereditary, it being only the constitution which predisposes to it that can be transmitted. But before practitioners were acquainted so accurately as at the present day with the relation which exists between chronic organic diseases and the acute inflamation which preceded them—before it was known that these chronic organic diseases, as well as the anatomical lesions which characterize them, are the same, somewhat changed and organised as those of the previous acute inflammation;—before this period what was the opinion entertained relative to these very lesions; or, to speak only of those of one organ, the heart, what was said as to the cause of its disorders? Aneurism was considered as one of the would-be hereditary affections, as tubercles are at the present day. However, hereditary transmission was not supposed to be the only cause capable of producing aneurism; other accidental ones were, perhaps, necessarily admitted; now it is the same with respect to tubercles, for those who think that they are hereditary are obliged to confess that, in certain cases, this mysterious germ developes itself spontaneously and accidentally, without their being able to say why or under what influence, except that in the majority of cases the individual is of a lymphatic temperament. Thus, this constitution, more or less developed, creates a greater or less predispo-

sition to contract the affection, so that, unfortunately, too often an individual may be attacked by a tubercular disease without any other member of his family having suffered from it. This, in my opinion, is the fundamental, and perhaps the only predisposing cause of tubercles.

ON THE SUPPOSED ADVANTAGES OF A KNOWLEDGE OF ANATOMY TO THE ARTIST.

By Dr. Knox, F.R.S.E., F.R.C.S.E.,

Corresponding Member of the French Academy of Medicine, and Lecturer on Anatomy and Physiology, &c. &c.

(Continued from page 208.)

III.—Sir Charles Bell.

When comparatively a young anatomist, but even then an artist of excellent taste, high aspirations, and the utmost delicacy of feeling, Sir Charles Bell published the first edition of his very beautiful work "The Anatomy and Philosophy of Expression, as connected with the Fine Arts." The second edition appeared as a posthumous work; it was revised and to a certain extent remodelled by its excellent author very shortly before his sudden death. Of this work it cannot be said that it offered any new views, promulgated any bold theory, or added any new and substantial proofs to the existing theories held respecting high and ancient art; or placed the importance of anatomy to the artist in any stronger light than what had been already done repeatedly by previous writers. Sir Charles had no new views on these subjects which I can discover; there is a vagueness, moreover, a wandering from the point, in his discourses an indirectness in his manner of stating what he thinks, which it must, I think, be conceded by all who attentively peruse his beautiful volume, irresistibly forces on the conviction of the reader the belief, that Sir Charles Bell had no clear idea of "the Theory of the Antique Statue;" that "he had wandered in search of truth, and had missed his way." However this may be, he maintained the extreme importance of a knowledge of anatomy to the artist; this point I shall examine here. As an artist and an anatomist in a certain sense, Sir Charles is entitled to a double share of our consideration. Sir Charles thought, and has expressed the opinion, that "Institutions, much more than climate, influence the faculties of man." The opposite was the theory of Hippocrates, and is a very ancient and much disputed dogma; it was discussed in its utmost latitude by Hippocrates, who assigned a share of influence to each, a greater share probably than either merits. Institutions are to a certain extent merely formed by races of men; those formed by despots never last long, unless they happen to govern men who are naturally slaves. The Anglo-Saxon of the United States shook off with the very earliest opportunity the military despotism which Britain attempted to exercise over his country, as she does over all her colonies: the blood of the race showed itself at once—had it been a Russian Colony, its dismemberment would never by any chance have happened. Climate influences man but little, and institutions not at all; they are the mere result of his own mind; they are effects, not causes. The idea that "the ruin of the Greeks might be owing to the conformation of the brain," Sir Charles calls ridiculous, and yet it is extremely difficult to see to what else it could be ascribed. He further adds, "the Greeks were not extirpated by the Roman conquests; the skulls of a people do not change." But it would not be difficult to show that the modern Greeks differ widely from the ancient Greeks, the men of Thermopylæ and Marathon; these have been extirpated, no doubt, not by the Romans, but by mere physiological causes. The cozening, cowardly, lying Greek of modern times is the Asiatic Greek, not the European. Look at the busts of the ancient Greeks which have come down to modern times, and say if in modern Greece you find these forms and faces? No one has ventured to say so. Where do you find in any of these ancient busts, of Hippocrates, for example, of Pericles, of Thucydides, of Aristotle, the convex physiognomy, half Jew, half Coptic, of the modern Greek, the projecting eye, the full heavy Egyptian lip, the semilunar forehead and face, the arched nose and full nostrils, beautiful in youth but sadly altered in age? Never. The ancient Greeks have most unquestionably disappeared: it matters not whether by the Roman conquests or otherwise. In a few centuries the Celtic race may in our Scottish highlands be entirely displaced and disappear, slinking away before the heavy, lumbering, but laborious and steady Saxon; then may some future Sir Charles say, how is this? The Celts were never exterminated by the British? See how institutions have changed their nature; from being warlike, sudden, and pugnacious, on the point of honour, and reckless, they have become cautious, slow of movement, persevering, accumulative! Sir Charles says that "the skulls of a people never change"; then they must have been constructed differently at first, a reflection on which Sir Charles does not venture, for it is admitted that different races of men have differently formed crania; and if the crania of nations (Sir Charles means races, of course), "do not change," then they must have *originally differed*—but Sir Charles does not venture to say so; indeed, the remarkable distinctions in races Sir Charles always shuns discussing. He fancied that "the Celtic Gaul of the Romans is now diminished to the remnant living in the mountainous districts of the extreme west of Europe." It is almost inconceivable that Sir Charles could have visited Central France, and more especially the districts of the Rhone, and failed to observe that the inhabitants are perfectly identical with the present inhabitants of northern Scotland and Wales. The Romans found the Celt on the Rhone and in Paris, and still in all his original character he occupies the same *locale*, unaltered, and unalterable by human contrivances; that is, human laws, institutions, and government. Annually, this inhabitant of Celtic Gaul becomes more and more, instead of less and less Celtic; now invading Africa, or threatening the Rhine and frontier; blustering at Ancona and Tahiti, and ready and willing to fight with any nation, savage or civilized.

But to return from a digression, caused by the discursive nature of "the Essays or Discourses" of Sir Charles, I shall endeavour, although it is by no means an easy task, to ascertain, 1st, what really were Sir Charles's ideas as to the nature of high art, and the essential character of Grecian or Antique beauty, and of beauty as it exists in nature—a distinction which has long been made, but with which I do not agree? 2d, What were his ideas as to the importance of a knowledge of anatomy to the artist? Much has been written, observes Sir Charles in his Essay IV., concerning "the ideal in art;" here is Cicognana's definition, as quoted by Sir Charles: "The ideal in art is nothing more than the imitation of an object as it ought to be in perfect nature, divested of the errors or distortions which secondary causes produce." He takes for granted that man, like everything else, has degenerated from the original design of nature, and that we ought to present his form as when he rose a newly created being, before misery, famine, cold, or excess of heat, had influence upon his frame. Perfect forms are no longer to be found in nature, but the Venus and Apollo, the Athletæ and the Hercules of ancient sculptors; these are perfect, recomposed into a beautiful whole. This theory of Cicognana, seemingly favoured by Sir Charles, does not merit a serious refutation. It is sufficient to observe that it is wholly hypothetical, and without a shadow of truth. To suppose men degenerated is an indirect attack on civilization and its presumed benefits; these, indeed, may not be many, still civilization has benefited a few: these few have not suffered—perfect forms should therefore be frequently found. And so they are, though Cicognana denies this; the term, recomposed, here used by the ingenious Italian betrays the old theory of Pliny and of others who preceded him; the recomposing or composing perfect figures formed of the perfect or finer portions of others. I have already endeavoured to show this theory to be untenable—besides, it is quite absurd to talk of "the beauty of the Farnese Hercules": this is an obvious abuse of language; the term Beauty can only be applied to the female form, and to the stages of youth, male and female, which represent her form: or, which comes to the same thing, those juvenile forms which the beautiful and perfect woman retains until that period when years seize on the frame, disfigure and distort it: producing a hideous obesity concealing all form, or betraying the skeleton—the presence of the still more dreaded skeleton and naked sinews—the frightful suggestive emblems of mortality and dissolution; dissolution, the end of all—dissolution, from which the mind, even the perfectly uninformed mind revolts, by an instinct in the formation of which reason takes no part. "No living head ever had the facial angle of the Jupiter, the Apollo, the Mercury, or the Venus."* This hasty assertion may easily be refuted by observing hundreds daily in the streets, whose profile is equal in all respects to the Venus, the Mercury, or the Apollo. The head of the Jupiter is ideal. A very prevalent idea (also adverted to by Sir Charles) is, "that there is in the face a character of nobleness observable, depending on the development of certain organs which indicate the prevalence of the higher qualities allied to thought, and therefore human; now this is merely a remnant of the old doctrine of association of ideas—that is, if it really mean anything more than this, (which I much doubt) namely, that the human species sees human qualities, be they noble or not is of no moment, in human faces only, and not in that of any other animal; man looks at man as one animal does at another; his feelings are towards his own species only. Now, in respect to knowledge of anatomy as essential to the artist,—to the good artist, Sir Charles thinks that such knowledge must not only be important to him, but essential. I have looked in vain for the arguments on which this opinion is based—anatomy, he thinks, may prove a remedy for tameness and mediocrity among artists; genius, inherent genius, is the only remedy for tameness and mediocrity—this is my opinion. Artists surely may draw what they see: let them attend to "the visible;" it alone charms. Leave the invisible to science; will the artist acquire vigour by caricaturing the human form or face? Will he improve the hand by letting the skeleton appear through the skin-clothed instrument? If anatomy were really essential to the artist, the comparative anatomical studies of the Landseers must have exceeded those of Baron Cuvier. Does any one believe that Paul Potter dissected a bull, before he painted that inimitable "Bull" of the Hagen collection? or Cooper? or Cuyp? or Rubens, who painted lions, but never dissected any? Neither ancient Greek nor ancient Roman artist knew anything of anatomy: this is an unquestioned fact, which admits of no kind of doubt.

Whilst a knowledge of anatomy must be, and of course is, useful to every human being, its profound study might wholly unfit the artist from representing nature "as she is;"—he would thus depart from the first principles of his art, the object of which is and always must be, to place before the cultivated minds "the beautiful in female form;" "the noble and dignified in man," as distinct from woman; the picturesque and grand in nature associated with an inherent feeling of awe and wonder; the grotesque and the amusing, addressed to the associations flowing from habits of education and external circumstances foreign to, but engrafted on our natures. Such must, I think, have been the opinions of those vested with the privilege of nominating to lectureship, on Pictorial Anatomy in artistic associations or academies. Sir Charles Bell was directly refused the lectureship of the London Academy; he was indirectly, (I may almost say directly), refused that of Edinburgh. *Anatomists* of every shade of reputation were refused these appointments; the patrons selecting as the person best qualified to infuse a taste for "high art" into the rising generation of artists, two general practitioners in the arts of physic and surgery.†

---

* Bell.

† It is deeply to be regretted that Sir Charles consented to the destruction of about thirty small volumes of MS. notes, written by his brother, Mr.

In conclusion, it may, I think, be justly remarked, that the work of Sir Charles Bell contains no strict analysis of the theory and beauty in the Antique marbles: and that he himself had no other view but what was founded on the old doctrine of the "association of ideas," to which he occasionally adds the still older ideas of "adaptation and design." In early life both brothers, John and Charles, commenced drawing the human figure dissected; taught to believe that in this way they might best acquire a knowledge of design; an ancient prejudice, an ancient error: from which the stronger mind of the elder brother John immediately emancipated itself (though at the age of 70,) the instant he contemplated the ancient statues of Greece now collected in modern Italy—the younger brother, Sir Charles followed, but could not, or would not, set his mind free from the trammels imposed by authority on his early youth.

John Bell, during his tour in Italy. Melancholy thoughts arise in the mind on reading such statements; here was one brother destroying the MSS. of another, the general scope of which, it is now evident to me, he did not understand.

AN ESSAY ON THE VARIOUS FORMS OF ASPHYXIA, OR SUSPENSION OF SOME OF THE PRINCIPAL POWERS OF ANIMAL LIFE, WITH GENERAL RULES FOR RESUSCITATION.

By Dr. Chas. Clay, Piccadilly, Manchester.

(Continued from page 271.)

Having made these general observations, I shall now proceed to the consideration of those circumstances generally regarded as tests of death, respecting which I have already stated that *no one* or *two* can be relied on, with the exception of putrefaction. To be of value, most of them must agree with each other; then correct conclusions may be arrived at.

The first circumstance I shall notice is the

SUSPENSION OF RESPIRATION.

Cessation of the respiratory powers, is an important item in distinguishing real from apparent death, and particularly when pulsation cannot be detected; of itself, however, it is more to be depended on than the apparent want of circulation, as its absence cannot possibly be continued for many minutes together without death occurring; and when it has really ceased for any time beyond a few minutes, there is no possibility of restoring the powers of life; on the contrary, provided there is respiration, *however feeble it may be*, though pulsation has apparently been absent for a considerable time, restoration may be effected, so true it is that

"Life is in the breath."

However feeble the powers of respiration may be, it is imperatively necessary to know that it *really exists*; when there has been great prostration of strength previously, considerable difficulties present themselves to a general observer, however, distinct the proofs may appear to those who are accustomed to such inquiries. The first duty, therefore, is to lay bare the chest and narrowly watch the surface, both in front view and in profile, when, if respiration really exists, it must necessarily produce the elevation and depression consequent on the enlargement and diminution of its internal capacity, produced by respiration. In this movement the ribs are slightly elevated, and the breast-bone pushed forward. The application of a mirror to the mouth as expressed in the beautiful quotation at the head of this chapter from the inimitable Shakespeare, is a test of no value, for if the mirror be warmer than the expired breath, the latter cannot possibly be condensed upon it, and the perspiration from the hand of the person holding it may affect its surface, so as to lead to a wrong conclusion. The mirror test has also been applied to persons in common syncope, without sullying its surface. Expiration through the nose with the mouth shut is much less liable to affect a mirror than when expired through the mouth. It has been a common practice with the vulgar to place a vessel of water on the chest, by the movements of which respiration is ascertained: it is certain the movements of the water might be sooner detected by a common observer than motions of the chest itself; but it must be borne in mind, that to put any weight on the chest, however trifling, whilst respiration is carried on *so very feebly, would be to extinguish it altogether*; instead of adding any weight, it is better to remove every encumbrance from the chest, to allow of free expansion and contraction. Equally unsafe is the test of feathers, light down, &c. placed on the mouth and nostrils. Prince Henry had reason to repent his precipitancy, by his depending on the want of motion in the feather placed at the mouth of his father. It is scarcely possible to place a body where respiration can be carried on, without slight disturbances existing in the surrounding atmosphere sufficient to produce motion in bodies so light, without respiration being present at all, and thus lead to wrong conclusions. Dullness or opacity in the eyes has also been spoken of with confidence as a test, but when it is known to be formed in cases for many hours before death, and that persons often recover after its formation, as also, that some persons' eyes have a peculiarly opake appearance without any serious disease existing to affect life; and, lastly, it must be recollected that, in many cases, even after death, this opacity does not appear at all, but on the contrary, the eyes are brighter and the power of contracting the pupil is retained for a time, as in cases of poisoning by hydrocyanic acid; a circumstance to be accounted for, by the suddenness of the death of an individual, perhaps in the prime of life, enabling the body to retain the power of organic sensibility for a longer time after death. Opacity of the eyes, therefore, is not to be received with too much confidence.

Coldness, and want of pulse, are also fallacious when taken by themselves; this is exemplified by the state of collapse in cholera asphyxia, in which the pulse is often not to be detected, and the coldness is almost equal to that of ice, and yet, from this state many have recovered.

Drowned persons are particularly cold, and pulseless, yet many are resuscitated. On the contrary, warmth is not altogether indicative of life, for in many cases of sudden death, viz., from apoplexy, the body is unusually warm for many hours after death, and instances have been related of sensible warmth being detected after two and three days. Paleness and lividity though often indicative of death, may yet be seen during life, as in the case of cholera asphyxia, where the fingers are bluely livid to an extreme, and the face, if not livid and blue, is ghastly pale. Rigidity is a valuable test, and can be relied on with much greater certainty than any other, with the exception of putrefaction; yet it may be mistaken for, and confounded with rigidity from other causes than death. In syncope and catalepsy there is rigidity, but it is not the cold rigidity attending death; on the contrary, it is accompanied by warmth. Rigidity arising from death is not immediate, but comes on gradually, whereas from disease it arises with the disease. In convulsive affections, where the rigid limb is altered in position, it will have a tendency, and often will resume its former state, whilst the rigid dead limb remains where it is placed. The only rigidity liable to be mistaken for death, is that of persons frozen; but there are differences which at once distinguish it, and which a practical observer may easily discover. A frozen person is rigid all over the body—the surface feels hard and stiff as a board, and the fatty matter of the breasts is equally hard; very forcible pressure on the skin with the tip of the finger leaves a hole which is long in filling up again. When the limbs are moved, a sort of crackling noise is heard, as though from small particles of ice in the fleshy substance of the limb. In the rigidity of death from other causes it is chiefly confined to the limbs. The breasts and belly retain a considerable degree of softness, and no crackling noise is heard when the limbs are altered in position. Indeed, few can mistake the cold clammy, dank feeling and rigidity attendant on death. When the above statements are duly considered, it will be acknowledged the only certain signs that a person is really dead, are the absence of respiration, and putrefaction. This brings us to the consideration of the nature of putrifaction itself. It is evident we can form no conclusions respecting putrefaction as to time; as has been already shewn the commencement of this process varies by many days according to the circumstances existing at, or previously to, death. What then are the signs by which putrefaction may be known? The following are the general circumstances attendant on this process in the order in which they occur. The body becomes softer and of a darker colour, there is greater degree of moisture, offensive odours are exhaled, which, after a time, have an ammoniacal smell; various parts appear dissolving, and rapidly changing in colour, becoming soft and gelatinous. There cannot remain a doubt of death under such appearances as these. From the various historical facts quoted, it is quite evident the length of time required to produce these changes is uncertain, depending much on the condition of the body as to disease or general health, age, and the manner of death. If we take a person in the prime of life, in full health, and dying very suddenly, the changes would occur generally at the times here stated, but they are not to be implicitly relied on. Chemical decomposition usually commences about the fourth or fifth day, when the skin on the palms of the hands and the balls of the thumbs begins to whiten. From the sixth to the eighth day, the backs of the hands and the soles of the feet whiten, and the face becomes softer and of a faded white. About the fifteenth day the face swells, and is reddish; a green patch is observed in the hollow pit, at the point of the breast bone; the inside of the hands and feet are quite white and wrinkled; the surface of the chest reddish. From the twenty-sixth day the face becomes darker, eyelids and lips swollen, neck green, and a dark spot as large as the hand, edged with green, on the centre of the chest; genitals distended with gas; hands and feet have the appearance of being parboiled; lungs distending the chest. About the fortieth day the skin detaches itself, and first at the connection of the hand with the wrist. At two months' end the body is covered with slime; face brown and enormously swelled; lips swollen and separated; teeth exposed. The most natural parts of the body at this time are the skin of the abdomen arms, and legs. Though I have given these signs of putrefaction, it will be only just to remark, that the duties connected with this work will have ceased long before these appearances are seen, indeed, it is only with the earliest premonitory symptoms of putrefaction, such as are analogous to appearances on the living body under certain circumstances, that the question of real or apparent death has any thing to do, for on the slightest indications of this revolting process all hopes of life are at an end. Hippocrates states, that real death is known by the face as follows; forehead wrinkled and dry, eye sunken, nose pointed and bordered with violet coloured or black circle, temples hollow, ears sticking up, lips fallen, cheeks sunken, chin wrinkled and hard, skin of a leaden tinge, hairs of the nose and eye lashes sprinkled with dust. These signs however are of no value taken separately since many of them are observed twenty four, or even forty eight hours *before death*, and many of them also are not observed in real death when it has been sudden. It is also necessary to remark that retention of life is less remarkable in man, than in the inferior orders of the animal kingdom, although the extraordinary cases adduced in the early part of this chapter would seem to furnish arguments to the contrary. It is, however, evident from all well ascertained facts, that the lower we descend in the scale of creation, the more remarkable is the power of retaining life under peculiar circumstances—or, in other words, those animals which appear to have the least development of animation whilst in their usual state of existence, present to us the greatest difficulties in the ascertainment of real from apparent death. For instance, one of the *rotifera*

(wheel animalcule) has been known to be from three to four years in the form of a shrivelled dead point, which may be broken in pieces with the point of a needle like a crystal of saline matter, and yet a drop of water will restore it to life and vigour. The preservation of life by hybernating animals, after lying for months in a state of torpor closely resembling death, is too well known to require further comment.

Having made these general observations, which are necessary to be advanced by way of caution against premature interment, and encouragement to those employed in the humane act of resuscitation, *not to withhold their exertions* in cases almost hopeless, whilst the slightest evidence remains to cast a doubt, as to whether the case be one of real death, a few concluding observations as to what must, and what must not, be done, will finish this, in my opinion, important chapter. More minute directions will be found under the head of each particular case of asphyxia as I proceed: the following brief remarks, therefore, will be of a general nature. In ascertaining whether life is extinct or not, we must first test the respiratory organs, by exposing the chest, allowing it space and freedom to dilate and contract, and removing from it every encumbrance or weight in the shape of clothing or otherwise; apply the ear or a stethoscope to various parts of the surface by which the action of the lungs in breathing, and the motions of the heart may be detected, if they exist, though carried on in the feeblest manner; narrowly watch the chest to ascertain its movements; feel for the pulse at the wrists, ankles, temples, but particularly by applying the ear over the region of the heart. As corroborative proofs, though of themselves valueless, I would add, test the mouth and nostrils with light bodies, as down, feathers, &c. It must be recollected in testing the circulation, that the pulse being absent is not to be received as conclusive, as in cases of cholera it is often absent from the limbs, though life is known to be present. The eyes must be examined as to their dulness and opacity (corroborative only), and whether the pupils will contract at the approach of a strong light, still bearing in mind that in real death from poisoning with prussic acid, the pupils of the eyes have been known to contract for some time after death at the approach of a strong light.

The temperature of the body must be noticed, taking care not to be deceived by the livid coldness of asphyxial cholera, or the warmth after death from apoplexy.

Paleness and lividity must be attended to, with the precaution of bearing in mind the ghastly paleness and blue lividity of the asphyxial cholera.

Rigidity must be particularly attended to, and great care taken, lest it be confounded with that of frozen persons, or that from convulsive diseases, when the limb restores itself to its former position; after forcible alteration apparent death only is to be suspected. The general stiffness of the body when frozen, its hard unyielding feel, and the crackling noise when moved, is very different from the common appearances of death. The rigidity of death comes on slowly, is confined chiefly to the limbs, has a peculiar cold dank feel; many parts of the body remain soft till it is beyond dispute dead. The surface of the body when pressed with the tip of the finger, pits, but fills up again slowly, though much more quickly than when frozen. The limbs lie in whatever position they are placed. If, after careful examination of these particulars, there is any doubt, let no persuasion induce you to consent that the body shall be interred, until signs of putrefaction are manifest, on which I have before treated at some length, when all doubt must cease, and when it may be truly said:

"So man lieth down, and riseth not till the heavens be no more; they shall not awake, nor be raised out of their sleep."

From what has been already said, it will be easily conceived what must not be done.

1. You are not to allow crowding anxiously round the body, destroying the small chance of respiring wholesome air. 2. You are not to put the body in an apartment where there is little or no free circulation of air. 3. The chest must be freed from all encumbrances, and nothing added by way of tests, such as the absurd custom of placing vessels of water to ascertain its movements, the very weight of which would, in all probability, destroy the small remains of respiration at a time when if it is carried on at all, *it must be with extreme feebleness.* 4. You are not to waste too much time in testing, but come to your conclusions as rapidly, and with as much certainty as the circumstances of the case will admit of, in order that if any remnants of mortality remain, they may be fostered by speedy means, properly applied, for their restoration according to the nature of the case. 5. Confidence is not to be placed individually on any one or two tests (with the exception of putrefaction); they must all, or nearly all agree with each other, before interment is consented to. And, lastly, let the exertions for resuscitating be rather over than under done; let them be continued rather too long, than fall short, it being a painful reflection to suppose *a few minutes more* might have accomplished the restoration of life: and as the difference of exertion for a few minutes extra, is trifling, and the reward (if successful) beyond all calculation, the best motto then is to persevere *a little beyond the last hope.* I feel the importance of these observations in their full force, and cannot but imagine, if carefully *acted up to*, the rare occurrence of live interment would be still more rare, if ever it could really happen.

My next subject will be the general Cause of Death, Artificial Respiration in Adults, New-born Infants, Syncope, &c. &c.

EXTRA UTERINE FOETATION.

Dr. Joseph Edmundson, of Carrick-on-Suir, has sent us the following case:—On Tuesday evening last, at ten o'clock, I was requested to visit a poor woman, named Kuvan, who had been in labour since four o'clock on Sunday morning (sixty-six hours).

She stated to me that this was her fifth pregnancy, that the full term of gestation had expired, but that she never had experienced such severe labour in any of her former confinements. Her countenance was expressive of great anxiety; extremities cold; tongue white and dry; pulse 130; very weak; abdominal tenderness, and great prostration of strength; no discharge of liquor amnii; vagina cool and moist; os uteri dilated to about the size of a crown piece. I thought I felt a head presentation; not having passed any water for several hours, I introduced the catheter, and drew off about ℥xij. of turbid fœtid urine.

I then left her, having directed her to use some stimulants, and to have heated bricks immediately applied to the feet.

Two o'clock.—Pulse 125; somewhat stronger; abdominal tenderness increased, particularly at the left side; os uteri in the same state; but I could not detect any presentation; slight hæmorrhage, about ℥iij. of blood, or perhaps a little more. On inquiry I was told that she had had one short violent pain, and that the uterus had not acted since; that the pain was succeeded by vomiting. I now looked upon it as a case of ruptured uterus; the prostration of strength was such that I did not feel myself justified in attempting to turn; I administered a small dose of tinct. opii and spt. ammon. aromat. to check the vomiting, and ordered the stimulants to be continued.

I visited her every two hours, until one o'clock, p m. Wednesday; the pulse was then a little firmer, but no other change had taken place; I determined to give her a chance, and make an attempt at turning the child. There had been no return of hæmorrhage; the vagina rather hot, but still moist and dilatable. Without much difficulty I introduced my fingers and thumb (as far as the metacarpus) into the uterus, but could not succeed further; the uterus was acting powerfully, notwithstanding my having given a dose of tinct. opii previously to, and having repeated it whilst attempting to turn. I was obliged to withdraw my hand, and desist from any further attempts; she sank rapidly, and died at half-past six o'clock the same evening.

I was requested at nine o'clock (two and a half hours after death) to remove the child, for the purpose of having it buried separately.

Having made an oblique incision in the left side of the abdomen, I discovered an extra-uterine fœtation. A fine full-grown female child was lying on the left side, between the intestines and the peritoneal lining of the abdominal parietes, the head being placed in the left iliac region. The infant was perfectly formed, and of the usual size, having lived to the full period. It had not undergone the slightest degree of decomposition, but the face was swollen and greatly contused.

The left Fallopian tube was ruptured to the extent of about two and a half inches; the uterus was greatly hypertrophied, being about the size of a fœtal head of the sixth month; the cavity in the uterus was about four inches long, and contained some clotted blood; the placenta appeared to be about the usual size.

From the time I had seen her, I could not detect any stethoscopic signs of fœtal life, and the mother told me that Monday was the last time she was sensible of the existence of the child.

DR. KNOX ON THE NOSTRILS OF THE HORSE.

Dr. Knox, in an elaborate paper on the Nostrils of the Horse, published in the *Veterinary Record*, describes a structure which he first observed in the great Northern whale, and which has an analogue in man. Having commenced by discriminating between the external opening of the nares, and the cavity which he calls the *vestibule*, Dr. Knox proceeds as follows:—"Now, from this vestibule towards the back and upper part there lead *two orifices* in the horse, both of which are indistinct during expiration or the collapsed state of the parts; nay, perhaps, are even closed hermetically, under some circumstances (as when the head is placed entirely under water); these orifices are, first, a superior one leading to 'the cavity of the false nostrils,' and a second opening differently shaped, and more like an enlarged slit, or wide fissure, leading into 'the cavity of the true nostrils,' this being the name I gave to the remaining part of the tube. This 'cavity of the true nostrils,' then, has two openings, one leading into it, the other out of it; one anteriorly into the 'cavity of the vestibule,' the other posteriorly into the pharynx. Attentive observation shews, that the two openings I have just spoken of, as leading from the vestibule backwards, are, to a certain extent separated from each other by a remarkable prolongation of what has usually been called integument, running apparently from near the edge of the external orifice to the inferior turbinated bone; that is, quite across the vestibule. When the *vestibule* is fully dilated, this singular fold is seen to rise up, and by so doing it renders much more apparent the inferior orifice leading into the cavity of the true nostrils; but in the collapsed state, this prolongation sinks down, and the orifice, that is the anterior opening of the true nostrils I speak of, is no longer visible. It is easy to see, that the orifice by which the false nostril communicates with the vestibule is bounded by, and the lower and inner wall of the cavity itself is partly formed by, the fibrous and elastic prolongation already alluded to, which, on being traced, leads to the anterior extremity of the lower turbinated bone to which it is attached. Even without dissection it may be ascertained to be a fold of mucous membrane rolled on itself, and containing evidently two structures,—a true cartilage, also turbinated or rolled on itself, posteriorly; anteriorly, a fibrous cord, also elastic. Into this spur-like cartilage and prolongation there is inserted a powerful, though short, semicircular muscle (the nasalis brevis of veterinarians), attached by its other extremity to the maxillary and intermaxillary bones. The action of this muscle is to withdraw the spur-shaped cartilage and its prolongation from the position it usually occupies, filling up nearly the slit-shaped opening leading from the vestibule into the true nostrils, by pulling it upwards and outwards upon the edge of the anterior maxillary bone; in this it is greatly aided by the other muscles acting as

dilators of the nostrils, or, to speak more precisely, *dilators of the vestibule*, whose influence, however, is chiefly exerted on the cartilaginous alæ. Whenever I ceased pulling on the muscle, the spur-shaped cartilage with its prolongation returned into its place, shutting up more or less completely the anterior opening of the true nostrils, or that leading into the vestibule. It must be particularly kept in view, that the fibrous prolongation of the spur-shaped cartilage is by its anterior extremity attached to the great alar cartilage, whose slightest motion therefore affects it."

Dr. Knox now divided the head vertically, and removed the septum narium with the left nostril, so as to obtain a view of the interior of the right nostril. "Looking at the right cavity from its inner side in the way I now speak of, it was evident that, whilst undisturbed or in the collapsed state, the spur-shaped cartilage closed in the extremity of the lower meatus of the nostrils; but when raised up by its appropriate muscle, it left this meatus free, shutting in the anterior part of the meatus above it. This curious play was admirable and striking. As covered by mucous membrane undisturbed, it looks like a continuation of the lower turbinated bone, and in one sense no doubt is so; but on stripping off the mucous membrane, a cartilage is discovered, which I have likened to a spur or sickle. This cartilage, which is of considerable length, extends from near the anterior extremity of the lower turbinated bone to a line corresponding to the extremity of the nasal bones. A fibrous and mucous prolongation extends from its anterior extremity quite to the great alar cartilage, thus completely crossing the vestibule." Dr. Knox has also "discovered another muscle so placed as to enable the horse forcibly and on emergencies to pull back the sickle or spur cartilage, so as more completely to block up the orifice it is intended to protect. This muscle is distinct and large, of a triangular or fan shape, with well-marked fleshy fibres: arising from the inner side of the inter-maxillary bone, it is firmly attached to the spur cartilage about the middle. On imitating its action by pulling at it, I found that it depressed very strongly the spur-shaped cartilage and its prolongation; that it was, in fact, the direct antagonist of the nasalis brevis placed on the exterior of the apparatus; that the latter draws the cartilage upwards and outwards; the former, or the internal, as forcibly drew it downwards and backwards."

Dr. Knox supposes this fibro-cartilaginous structure to fill the important purpose in the whale of acting as a bolster to plug up entirely the cavity of the nostrils, when that animal is exposed to the great pressure caused by its mode of life. When it comes to the surface to breathe, the bolster is withdrawn by a muscle answering to our dilatores narium, and this is the first act of respiration. "The arrangement in the horse is somewhat different; but by means of the muscle I have described, the horse, in all probability, possesses the means of cutting off temporarily all communication between the vestibule and the great or true chambers of the nostrils. This may aid in protecting him somewhat from dust and flies. This, which in the whale is constant, regular, and complete, may be in the horse and man only an occasional occurrence; it being always remembered, however, that the first act of respiration in him, as well as in other animals, is to dilate the vestibule and its orifice, and to withdraw, by this very dilatation, from the entrance of the true nostrils the spur-shaped cartilage and its prolongation, placed there for its protection." Dr. Knox will, in a future memoir on this subject, consider the means of protection afforded to the human nostrils.

We are informed, that the prize placed at the disposal of the President and Fellows of King and Queen's College of Physicians, by the Lord Chancellor of Ireland, has been awarded to Dr. Joseph Williams, of Tavistock Square, London, for the best essay "on the Use of Narcotics, and other Remedial Agents, calculated to Produce Sleep in the Treatment of Insanity."

PROGRESS OF FRENCH SCIENCE.

FROM OUR OWN CORRESPONDENT.

Academy of Medicine; Sitting of the 17th June. M. Caventou in the chair.

On Pellagra.—Dr. Gibert addressed a letter, in which he states that the case of pellagra, observed for the first time in Paris in 1842, at the Hospital St. Louis, though published by his leave by Dr. T. Roussel (then *interne* under him) in the *Revue Médicale*, was compiled under his superintendence, it being mentioned at that time by him to the Academy, and subsequently placed at the disposal of Dr. Jolly, who recorded it in his report. Consequently, it is not correct to state: 1° that this fact was published a year before that observed by him in the same hospital; and 2° that it was not known by Dr Jolly, reporter of the Committee named by the Academy.

On Pestis.—Dr. Aubert Roche writes to request the committee named to examine the documents relative to the plague to present its report; this is especially necessary from the fact of the Minister of Agriculture and Commerce having stated at the Chamber of Deputies, that the law on quarantines could not be modified until the Academy of Medecine had given its opinion. Dr. Rochoux: Since government seems disposed to introduce some amelioration in the quarantine laws, it is the duty of the Academy to promote it as much as possible, and to hasten this, the Committee ought to present its report as soon as convenient. Dr. Dubois of Amiens: The Committee does all it can to comply with the wishes of the Minister. Dr. Ferrus stated that the reason why the report was delayed was not on account of the want of will, but owing to the difficulties attendant on the subject, and added that in spite of the numerous reclamations, the Committee will examine this important question with all the care and attention it deserves.

On Wounds of the Liver.—Professor Gerdy read a report on a memoir of Dr. Roux, of St. Petersburgh, on wounds of the liver; the author, said the learned reporter, indicates two means by which the hæmorrhage may be stopped, and the effusion of blood evacuated without giving rise to fatal peritonitis. Conclusion, to thank the author for his communication; to place his name on the list of candidates as correspondent, and to insert his memoir in the Bulletin. M. Dupuy mentioned that one of the best styptic means he knew of was cerebral substance added to water, and injected in the veins; that it acts in a similar way to corrosive sublimate, by coagulating the albumen: it is, however, far more efficacious. Dr. Dubois of Amiens proposed sending the memoir to the Comité de Publication, and inserting the report in the *Bulletin*. After some further remarks from Dr. Castel and Professor Gerdy, the two first conclusions as presented by the reporter, and the third, modified by Dr. Dubois of Amiens, were adopted.

Paris, June 26, 1845.

On Diseases of the Eye, by Professor Velpeau.—*Chronic Iritis*—This affection is still involved in much obscurity. It has seldom been studied, except as a sequel to acute iritis, although it is not uncommon to observe patients in whom the disease seems to commence in the chronic form. Thus, sometimes the pupil becomes deformed, assuming an angular or oval shape, loses its mobility, and presents radiated filaments like threads, extending from the lens to the iris, or small cloudy flakes, when the patient has never been affected with inflammation of the eye. These appearances must evidently have been preceded by the insidious and slow development of the phlegmasia, and muscæ volitantes are very often, in my opinion, owing to this cause. In these cases, the iris seldom offers its natural hue, it is as if shrivelled. I have likewise sometimes seen a slight ring of a very pale red colour, and in all these cases I think that iritis exists, though they have been classed among the amauroses. *Symptoms*—The characters by which chronic iritis may be distinguished are: deformity and immobility of the pupil; change of colour, with sometimes a mist before the eye; presence of filaments, flakes, or stripes; photophobia, epiphora; no action of the pupil, when exposed to alternate light and shade. These symptoms ought never to be neglected, the more so as the disease often develops itself unperceived, or is confounded with amaurosis. *Causes*—Are but little known; the affection proceeds slowly and insensibly, and is often only discovered when it has lasted some time. It is for this reason that the causes were supposed to be constitutional. Thus, Larrey in France, and the German and English oculists supposed that it was always produced by constitutional syphilis. Now, though it is often true that it is observed in persons who have been affected with lues venerea, yet mercury rarely effects a cure, contrary to the conclusion which ought to be drawn from this fact. I have prescribed an antisyphilitic treatment in a great many cases, but though I did not find it often efficacious, still I do not mean to say that syphilis may not be considered as one of the causes of the disease, for in studying lues venerea with care, we often find, that it leaves after it certain modifications in the system, even notwithstanding the cure has been obtained by a most methodic treatment. For instance, if we examine what takes place in the urethra after one or several attacks of gonorrhœa, we may remark, that stricture exists, though the primitive disease had long before disappeared, leaving after it lesions on which the treatment has no effect. Do buboes, though cured, hinder engorgements or adhesions from persisting? These pathological conditions will not always disappear, even when the syphilis has been successfully combated. These remarks are equally applicable to iritis, since analogous phenomena take place; for if anatomical lesions are produced by syphilis, so iritis is followed by inflammation of the eye, and when it lasts some time, by flakes and filamentous adhesions between the iris and the capsule of the lens, and if the sight be restored, it is only in those cases in which the iris has not undergone any alteration, and does not offer the flakes and adhesions just alluded to. It may, therefore, be concluded, that even although it is proved beyond a doubt, that syphilis is the cause of the iritis, still there is not proof sufficient to permit our asserting that it may be cured by a course of mercury. Finally, as to the non-restoration of the organ to its normal functions, this is not peculiar to iritis, for it may take place in keratitis, as stated in a previous lecture. *Treatment*—When speaking of acute iritis I stated, that two remedies principally seemed to have a very beneficial effect; this, unfortunately, is far from being the case in the chronic form, which is far more serious, and more difficult of cure. The treatment I have adopted in this disease is: leeches to the temples, or on the mastoid processes, sometimes a small quantity of blood from the arm; purgatives; revulsives, which are more efficacious in the chronic than in the acute form of iritis; the most useful are temporary blisters on the forehead, just above the orbit; cupping at the nape of the neck; sinapisms on the lower limbs; the apparatus invented by Dr. Junot; issues or setons on the nape of the neck; moxas behind the ears, or what is still better, and which I strenuously recommend to the attention of the profession, an issue just below the occipital tubercle. I have found it more advantageous than the seton, as there is in this spot a mass of fatty cellular substance, continuous with that of the dura mater, and at the same time, it is more convenient, as it may be hid by the hair—a circumstance much to be desired, especially in women. There is another remedy which ought to be employed with those just mentioned, and which possesses great efficacy in chronic iritis,—I mean belladonna, which, as I have already stated, must be prescribed in a peculiar mode, in order to reap all the benefit possible from it. The object being to dilate the pupil, it must be given at intervals, not in a continuous manner, for this substance becomes inactive when it has been administered some time, unless the dose is increased so as to render it dangerous. If, then, it is administered at the same dose, it soon ceases to act, and the dragging produced by the dilatation of the iris gradually diminishes, and finally disappears. On the contrary, if an interval is allowed to elapse between each dose—a week, for instance—it produces a salutary effect on the iris, and by means of this intermittent dilatation, very often the adhesions caused by the disease are de-

stroyed. If the irritation is still intense, emollient collyria and ointments, containing opium and mercury, must be had recourse to, not forgetting, however, that the pathological alterations caused by chronic iritis, do not always disappear with the disease: this makes it so dangerous. As to the phlegmasiæ of the other membranes of the eye, they are so obscure that the opinions of practitioners vary considerably. I, therefore, could say little or nothing practically useful respecting them, and consequently prefer recapitulating, in a few words, all that has been stated on diseases of the the eye, with which I will close this course. *Recapitulation*—The various phlegmasiæ of the eye may be divided into: 1° Inflammation of the lids; 2° Inflammation of the conjunctiva; 3° Inflammation of the cornea; 4° Inflammation of the iris. 1° *Inflammation of the lids*, or *blepharitis*—(*a*) of the inner surface, subdivided into mucosa, granulosa, and glandulosa; (*b*) of the edges, subdivided into folliculosa, furfuracea, exulcerosa. 2° *Inflammation of the conjunctiva*, or conjunctivitis—(*a*) c. simplex, characterised by an arborescent violet red—membrane mobile—colour deeper in the oculo-palpebral furrow; (*b*) c. neonatorum, characters, swelling, secretion of yellowish or greenish pus; (*c*) c. blenorrhagica, same characters as the preceding, except that it commences usually on the ocular conjunctiva, whilst the former commences on the palpebral. 3° *Inflammation of the cornea*, or *keratitis*, subdivided into general, partial, ulcerated, and diffused—characters, epiphora, photophobia, pain, radiated redness. 4° *Inflammation of the iris*, or *iritis*, subdivided into acute, chronic, and specific—characters, circle surrounding the pupil slightly red, pain in the head, change of colour of the iris, irregularity of the pupil. The treatment is, in blepharitis mucosa, emollients, purgatives, venesection; blepharitis granulosa is very difficult of cure—sulphas zinci, sulphas ferri, azotas argenti; blepharitis glandulosa, more serious than the first, less so than the latter—styptic ointments and collyria. Conjunctivitis requires the use of azotate of silver, especially the purulent form, in which this salt must be used in the form of strong solutions. Keratitis, collyria, and ointments are of very little use; but general and local bleeding, revulsives, such as setons, issues, blisters to the forehead; calomel may be employed with advantage. Finally, as to iritis, I have described it too recently to need any repetition.

Caries of the Vertebræ (Pott's Disease)—Case recorded by Dr. Serrier, ex-Chef de Clinique of the Marseilles Hospital.—M. ætat. 18; husbandman; of scrofulous constitution; entered the Hotel Dieu, Marseilles, on the 11th of Jan., 1845. Four years previously he received a violent blow with a stick on his loins, which caused him to faint and remain insensible for ten minutes; this was followed by intense pain and impossibility of walking erect. Five or six months after, a hard tumour, formed by distortion of the lumbar vertebræ appeared for which he sought medical aid; four moxas were applied, and an appropriate internal treatment was prescribed, which only caused a slight improvement, for soon after a tumour appeared at the superior and anterior portion of the right thigh, which increased rapidly in size, and obliged the patient to enter the hospital. When examined, the following symptoms were remarked: a tumour of an ovoid form just above the groin, extended from the anterior superior spinous process of the ilium to the middle of the thigh in the direction of the sartorius muscle; fluctuation very manifest, skin natural colour; on placing the patient on his abdomen, it was found to reach backwards to the buttocks; a tumour of a similar nature at the upper part of the left thigh; curvature of the lumbar vertebræ two inches in length; when walking, the body leans forwards, the right lower limb is dragged, and the tops of the toes turned inwards. 15th January: about 1lb. of a white, creamy, healthy pus was drawn from the tumour—19th, abscess; has filled again the skin being thin, a new opening was made; pus flaky, not so natural—29th, death. *Autopsy.*—Tubercles at the apex of both lungs; abscess in the spleen; digestive canal sound; psoas muscles replaced by two large fluctuating tumours, which when opened allowed an immense quantity of greyish fetid pus to escape, walls two lines thick and lined with a blackish, velvety looking false membrane. On the left side the tumour commenced at the upper insertion of the psoas muscle, whose fibres were completely destroyed; opposite to the crural arch it became smaller, but increased afterwards in size, and extended along the upper part of the thigh to the trochanter minor; on the right side the lesions were of a similar nature, but not to such an extent: the sides of the two last dorsal vertebræ were slightly wasted; the body of the first lumbar quite soft; those of the second and third had completely disappeared; those of the fourth and fifth nearly so, and the latter contained a considerable quantity of softened tubercular matter.—(*Gazette des Hopitaux.*)

On the Treatment of Venereal Vegetations; by Dr. Vidal de Cassis, Surgeon to the *Hospital du Midi.*—The difficulty with which these vegetations are cured, and the frequent refusal of the patient to allow excision, cauterization or ligature (generally very painful,) caused Dr. V., to prescribe the following powder:—

R. Alumin. usti Pulv. junip. pr. sabin. aa. ʒij. ft pulvis, bis in die applicand.

The quantity of the former must be increased until it is double that of the latter. The vegetations are sprinkled with the powder, and except when they are on the parts covered by the prepuce, a simple dressing must be applied. The result is first dryness, followed by withering and loss of cohesion, so much so, that on touching them they crumble away without the least pain. Finally, though this method may not be applicable to every case, still as it does not cause pain, diminishes the number of the vegetations, (which is sometimes considerable) and perhaps will facilitate any future operation, it ought not to be neglected.—(*Annales de la Chirurgie.*)

On Calculi of the Nostrils (*Rhinolithes*—Graaf, *Dacriolithes*, Desmarres.) By M. Demarquay, *Aide d'Anatomie* at the Faculty of Medicine, Paris, *interne* of the hospitals, &c. The author, after giving the analysis of the mucus of the nose according to Berzelius: composition—

Peculiar substance	5·33
An extract soluble in alcohol, and an alcaline lactate	0·30
Chloride of sodium and potassium	0·50
An extract soluble in water with traces of albumen and a phosphate	0·35
Soda	0·09
Water	93·37

And that of the tears, according to Fourcroy and Vauquelin: composition—water, 0·99; solid matter, 0·01: considers—1° *The history.* In this chapter all the authors who have published cases on the subject are enumerated—Jos. Mathias de Gardi in 1502; Thomas Bartholinus in 1654 (two cases); Clauder in 1685; Kern 1700; Vitus Reidlinus in 1706; Wepfer in 1727; Ruysch in 1733; Plater in 1736; Horn in 1788; Dr. Savialcs in 1814; Dr. Graeffe in 1828; M. Thouret, jun. in 1829; Dr. Axman same year; Sir B. Brodie in 1844, and the case of Professor Blandin, which was the cause of the researches of the author. In some a foreign body formed the nucleus—generally a cherry-stone—in others nothing. 2° *Seat.*—These calculi are developed in the right as well as the left nostril, in the upper meatus as well as in the lower; and though, perhaps, more frequently in the latter, still they may commence higher up, for instance, in the frontal, and perhaps, in the maxillary, sinuses, and thence descend into the fossæ narium. They may fill up the nostrils, push the septum towards the opposite side, and even destroy it. Their size is from that of a lentil to a pigeon's egg; their number varies; generally there is but one, but sometimes several exist at the same time; their surface is always uneven. 3° *Composition.* Analysed—1° by Dr. Axman—

Animal matter, albumen, mucilage, fibrin, fat, osmazome	0·35
Phosphate of lime	6·8
Carbonate of lime	3·25
Carbonate of magnesia	1·25
Soda, muriate of soda, and oxyde of iron, traces.	

2° By Prout, in Sir B. Brodie's case, which contained mucus and phosphate of lime. 3° By M. Bouchardat. Professor Blandin's case, mucus; phosphates of lime and magnesia; carbonates of lime and magnesia; chloride of sodium; traces of carbonate of soda. These analyses show that their composition is very similar to that of the mucus of the nose and the tears. 4° *Causes*, in general, very obscure; Graeffe supposed them to be produced by a rheumatic or gouty constitution; this, however, is more than doubtful; by the modification produced in the secretions by chronic inflammation of the nostrils, or lachrymal glands; narrowness of the nostrils, especially of the meatus inferior; foreign bodies. 5° *Symptoms*—dryness of the nostrils; sense of weight and stoppage; difficulty of breathing, sometimes intense; intermittent pain in the forehead; inflammation of the neighbouring parts; abundant mucous, and often purulent, discharge; in the latter case the odour is so offensive that the disease may be taken for ozæna; swelling of the affected side; eye filled with tears, if the lachrymal ducts become obstructed or participate in the inflammation; this is more apparent when the obstruction occupies the meatus inferior; it must, however, always be remembered that the phlegmasia may be the cause, not the effect; finally, whenever it is within reach of a sound, or a polypus forceps, the dull characteristic sound may be obtained by percussion. 6° *Diagnosis*, in general, not difficult, as the calculus may be easily discovered by an attentive examination. 7° *Treatment.*—The first thing to be done is to remove the calculus; this may be effected with an ordinary dissecting forceps, or a polypus forceps; it must be extracted with great care, on account of the inequalities of its surface, and sometimes on account of its size,—this accomplished, the consecutive symptoms must be combated by emollient and discutient injections; finally, if it appears to be owing to a general cause, this must undergo appropriate treatment. (*Archives de Medecine.*)

Cauterization of the Mucous Membrane of the Vagina, as a Cure for Leucorrhœa. By F. Devay, M.D., Physician to the Lyons Hospital.—According to the author, whenever in chronic leucorrhœa the usual local and general remedies fail, the practitioner may be certain, when the cause does not extend beyond the vagina, (which alone will be studied in this article) that there is a considerable lesion of the mucous membrane of that canal, or an hypertrophy of its tissue, and especially of its follicles. This affection is apparently atonic in its nature, and brings with it a laxity of the mucous membrane, and though not productive of immediate danger, always creates disturbance in the health, and, weakens the patient. On examination with the speculum, spots of a livid red and sometimes slightly blue colour, covered by a thick mucus, are to be perceived here and there on the surface of the vagina, and the follicles form visible lacunæ. This affection may be produced by a local or general cause: *local*—here it is consecutive on blenorrhagia; chronic inflammation; granulations of the cervix uteri; the presence of a pessary; an accouchement, &c.; *general*—lymphatic temperament; predisposition to contract catarrhal affections; habitation of a low and damp room, deprived of the sun's rays; cold continually applied to the feet or body generally; constant irritation of one of the pelvic viscera. To obtain a cure, Dr. Devay recommends cauterization with the azotate of silver, first proposed by Dr. Ricord, who employed it in chronic vaginal blenorrhagia with slight lesion of the membrane—in that complicated with lesions of tissues, erosions, ulcerations, &c.; in the acute form sometimes at the commencement, or at a somewhat later stage. The mode in which cauterization is performed, is as follows: the speculum is introduced and the cervix uteri exposed to view; this must be touched with the lunar caustic if requisite, after which as the instrument is withdrawn, the portions of the vagina which present the red spots must be gently cauterised by applying the nitrate once or twice to them; this is repeated a second time; finally the speculum having been removed, the labia must be separated, and the orifice of the vagina cauterized; no consecutive inflammation

was produced, although the operation was repeated once or twice a week. During the intervals, injections of cold water, or a very weak solution of acetate of lead were used. By this mode of treatment a cure was obtained, on an average in a month or six weeks. Six cases are recorded as proofs of the efficacy of this method.—*Gazette Medicale.*

Academy of Sciences. Sitting of the 22nd June.—M. Elie de Beaumont in the chair.—Received. [illegible] ort on the Coast Survey, and reports [illegible] trustees of the Philadelphia Gas Works, presented by John C. Cropon Esq., the former in the name of Professor Bache, the latter in his own.

Improvements in the Navigation of the River Clyde. By W. Bald, Civil Engineer, F.R.S.E., F.G.S.L., &c.—The author after enumerating the reports presented on the navigation of the Clyde, the impediments that have been removed; the amount of shipping; the number of boats employed in deepening and improving the river—and the quantity of sand, mud, &c., taken away, states that the improvements are due, 1° to the construction of jetties which determined the width of the channel, and increased the cleansing power of the river, (commenced in 1768). 2° to the construction of longitudinal dykes, (commenced in 1799) by which the velocity of the water was equalized, thereby removing and preventing the formation of shoals and pools. 3° To the dredging steam boats and diving bells, in removing all kinds of shoals, banks, and bars from the navigation, which the jetties and longitudinal dykes could not accomplish by increasing the cleansing power of the river.

On the Culture of the Sugar Cane in Andalusia. By M. Ramon de la Sagra, Corresponding Member of the Academy.—Two kinds of cane are cultivated on the coast of Andalusia from Almeria to Marbella, near the Strait of Gibraltar. 1° The smaller kind cultivated in the West Indies, and before the conquest in Spain, and the Canary Islands. 2°. the larger species brought from Otaheite in 1816. The quantity of sugar contained in the cane is on an average from ten to twelve per cent., of which, two-fifths are white, or brown sugar, and three-fifths molasses. Four millions of pounds are annually made on the nine remaining plantations, *i. e.*, 800,000 lbs. of white sugar, 800,000 lbs. of brown sugar, and the remainder molasses. A greater portion of land is about to be cultivated, so that it is to be hoped that the coast of Andalusia will, ere long, produce sufficient sugar to supply the wants of Spain.

Academy of Medicine. Sitting of the 23d of June.—M. Caventou in the chair.

On Pestis.—Dr. Tanchou addressed a letter on this subject, in which he states, that far from coinciding with those who request the Committee to hasten their report, he considered it advisable to consult not only city, but likewise country practitioners, military and naval surgeons, and travellers, as well as all persons who, by their knowledge on the subject, may elucidate the question which is an important one, inasmuch as it may permit the importation of a disease into France, and become a scourge to the country. Furthermore, he thinks it surprizing that the legislature is on the point of suppressing the lazarettos, without taking into consideration the services they have rendered, without examining whether it is not sufficient to modify our sanatory laws, and without considering whether it would not be more advisable to attack the scourge at its source, conjointly with other foreign powers. Finally, he concluded by saying, that the Academy ought not to allow the medical body to be deprived of the right of giving its opinion in this question, and to permit no one's taking this right from them without rendering them responsible for the dangers which may result. Dr. Prus remarked that, notwithstanding the desire of the Academy to hear the report of the committee, it was impossible for it to proceed with greater rapidity;—that, very recently, important documents had been received from Egypt, and others were daily expected. Finally, that the subject would be examined with all the care and attention requisite.

On an Epidemic of Typhoid Fever.—Dr. Poiseuille read a report on this subject. After mentioning the numerous deficiencies which exist in the memoir, the reporter concluded by proposing an answer to the Minister of Agriculture and Commerce, that it contained nothing new nor worthy of attention. Dr. Rochoux, from the description given of the disease considered that there was an error of diagnosis, M. Dupuy was of the same opinion, the more so as no *post mortem* examination was performed, and as the author himself stated that the epidemic followed the course of the river. Might it not have been intermittent fever? Dr. Dubois of Amiens, asked whether the term, error of diagnosis, might not be suppressed, considering that it was addressed to a colleague. Dr. Rochoux persisted in retaining it. Dr. Gueneau de Mussy gave some topographical details relative to the localities in which the disease was found, which were contrary to those of the author. Conclusions adopted.

The chairman informed the Academy, that Dr. Gaetani Bey, chief-physician of the Viceroy of Egypt, was present.

On Typhoid Fever.—Dr. Gaulthier de Claubry read a memoir on this subject, in which he endeavoured to prove—1° That typhoid fever and typhus are identical—2° That the former like the latter is contagious. After demonstrating the analogy between the symptoms and pathology of the two, the author quoted, in favor of contagion, cases from his own practice, the opinions of Drs. Chomel, Louis, Moreau, Andral, and Jolly, and stated that as the disease attacks an individual but once, and as it is very frequent during childhood, most adults may expose themselves to its influence without danger. Dr. Rochoux did not agree with his colleague, since, in his opinion, the two diseases differ essentially.—1° *In their causes.* Thus, how is typhus developed? By vitiation of the air by a number of individuals, in a small space, and by contagion. This has been admitted by all writers from Thucydides, who gave an admirable description of the Athenian Plague, down to the present time. Now, nothing similar is observed in dothinenteritis. it reigns in the gilded apartment as well as under the peasant's thatched roof,—in the best as well as the worst hygienic conditions. As to contagion, it does not exist, for no instance has been recorded for the last thirty years in the Parisian Hospitals. Typhus attacks all ages; Dr. Delaroche died at 70, Titian at 90; dothinenteritis is seldom seen after 50. The former appears suddenly, seizes upon the inhabitants of the country, as well as on strangers; the latter, on the contrary, is chiefly observed in large towns, and especially among young people, recently arrived, who are not yet seasoned.—2° *In their symptoms.* Who ever remarked in dothinenteritis the peculiar characteristic delirium of typhus, the brilliancy of the eyes, the petechial eruption; this last being very different from the purple or roseate spots observed in dothinenteritis. —3° *In their mode of development.* The rapidity with which typhus goes through its stages is sometimes terrible, since it may end fatally in thirty-six, twenty-four, twelve, and sometimes in four or five hours. Dothinenteritis is much longer; it lasts, on an average, twenty-one days, whereas typhus requires only fourteen days.—4° *In their pathology.* None of the facts are conclusive; as to those published previous to 1811, they are more than doubtful. —5° *In their prophylactic treatment.* By flight we may preserve ourselves from typhus; this is impossible in dothinenteritis. Finally, Dr. Rochoux considered the denomination of typhoid fever to be a scientific misfortune. Dr. Gaulthier de Claubry did not like to hear Dr. Rochoux cast a stigma on all the facts published previous to 1811, for it was at that time that the work of Petit and Serres appeared, establishing the knowledge of this subject. Among modern authors Landouzy may be quoted. As to the other objections, they were refuted in a work published by him on this disease; and it is therein shewn that the intensity of the symptoms is not sufficient to cause the two affections to be considered as non-identical; consequently he maintained his opinion to be correct. Dr. Merat remarked that Corvisart, Bayle, Dupuytren, were in 1811 at the head of the anatomical school, he therefore considered that the opinions of that period were deserving of more attention than Dr. Rochoux seemed disposed to accord them. Dr. Castel, after quoting sentences from Lancisi, Rœderer, and Wagler, stated, that, in his opinion typhoid fever may present all kinds of forms, become contagious by its intensity and by the number of cases, and as to the identity which exists between the two diseases under consideration, it may be said to exist in every species of fever. This discussion will be resumed at the next sitting.

Eclampsia Puerperalis.—Dr. Hullin, of Mortagne, read some practical remarks on a case of this affection, cured by repeated baths and cold affusions on the head; the accouchement, though it did not cause the convulsions to cease, still rendered them less intense.

GARLAND DE BEAUMONT, D.M.P., B.L., & S., &c.
Honorary Physician to the Spanish Embassy.

PROGRESS OF GERMAN MEDICAL SCIENCE.

By SIGISMUND SUTRO, M.D.

On the Urine and Blood after the Internal Use of Iodine. After small doses of iodide of potassium, or of iodine, the urine becomes paler; after larger doses it has a darker yellow, often a yellowish brown colour, and is clear of a weak or normal acid re-action, soon however becoming alkaline and turbid; uric acid, ammonia, and ammoniaco-magnesian phosphate being deposited as sediment. The specific gravity is frequently below the average. The urea is generally increased in quantity; the uric acid varies according to the more or less inflammatory condition of the patient. The chlorides are found in greater number as well as the salts of ammonia, and the extractive substances (phlogistic and azotised urea); the quantity of iodine administered is found almost immediately afterwards in the urine. Analysis of urine in constitutional syphilis after the exhibition of iodine and iodide of potassium for three weeks. The patient, ætat. 38, had suffered in 1829 from gonorrhœa and bubo, in 1838 from pains and swellings in the bones, which yielded to the decoction of Zittman; in 1841 similar pains returned in the clavicle, and were combated by mercury; in 1843 they reappeared, and did not yield to the exhibition of that mineral. The bones of the nose becoming also affected, the patient took one scruple of iodide of potassium, then ten grains of that salt, with five grains of iodine, and lastly one drachm of the iodide with one grain of iodine, his principal diet being fruit and roast meat. Analysis of the urine on the 22nd January;—a normal quantity of a dark yellow, inodorous and naturally acid urine was secreted, the specific gravity of which was=1015; (the patient had taken two scruples of iodide of potassium in three ounces of distilled water.) Nitric acid neither showed *albumen*, nor biliphacine, but with chromic acid it showed a marked iodine reaction, as well as of xyloidine. The urine contained in 1000 parts;

Water..................	974,80
Solid Substances	25,20
Urea	7,737
Uric Acid	0,310
Extractive Matter and Sal-Ammoniac	6,433
Salts (uninfluenced by fire, and Iodide of Potassium)	10,520

On the 26th of January (the patient had taken till then two scruples of iodide of potassium with half a grain of iodine in three ounces of water) the urine was very dark yellow, quite clear, of normal smell, secretion diminished. Reaction slightly alkaline. Spec. grav. 1021; it contained:—

Water..................	954,40
Solid Substances	45,60
Urea	13,82
Uric Acid	0,51
Extractive Matter and Sal Ammoniac............	12,15
Salts (unacted on by fire) and Iodide of Potassium	19,32

On the 31st of January the specific gravity of the yellow alkaline urine, discharged in the morning

=1017, the urine discharged at night =1021. Within twenty-four hours 24,5 ounces (850,0 grammes) were discharged; 200 grammes having been evaporated, the residue was dissolved in water, filtered, the filtrate washed and mixed with ammonia (till the liquid displayed strong alkaline re-action) and precipitated with nitrate of silver; the precipitate washed with liquor ammoniæ, dried and weighed. Thus, 0,94 of iodide of silver was obtained, containing 0,507 of iodine; thus, 1000 parts of urine contain 2,535 of pure iodine, or 3,323 of iodide of potassium. The 850 grammes consequently contain: iodide of potassium, 2,824 grammes, or in 24,5 ounces, 38,689 grains. The iodine being always found in urine in the form of iodide of potassium, the author calculated the half grain of iodine as iodide of potassium. The patient had taken hydriod. potassæ, grains 40,656; thus, 38,689 grains being discharged by urine, only 1,967 grains entered the blood, and was discharged by the saliva, perspiration, &c. If the patient perspire strongly, more iodine is undoubtedly discharged by evaporation. *Iodine in the blood.* The blood of patients who had taken an average quantity of one scruple of iodine was examined. If the author added starch to the serum of the blood, and then nitric acid, or *vice versa*, he did not find any iodine. But when he dropped the serum with nitric acid on chromate of xyloidine, a fine violet-colour was exhibited; a similar phenomenon was found after the serum was freed from albumen by boiling and filtering. From the circumstance that the reaction of iodine is more manifested, if hæmato-globuline be combined with the serum, the author concludes, that the salt of iodine is more communicable to the former than to the serum. The quantity of iodine in the blood is so small that it cannot be determined, even when large quantities are taken, and found very soon after in the urine. This leads again to the conclusion, that this remedy is more readily excreted than taken into the system. Even the microscope shews no particular change in the blood. (*Dr. Heller in Heller's Archiv fur Physik, &c.*)

Method of Discovering very small Quantities of Iodine in the Blood.—By the usual method of employing nitrate of mercury, the chlorine of the common salt contained in the blood is undoubtedly also precipitated. 1. *On the iodide of amylum.* Many erroneously believe the starch to be coloured violet by iodine as iodide of amylum, whereas it is only a mixture of an *indefinite* quantity of starch with iodide of amylum. This is easily recognised under the microscope, when uncoloured globules are seen near the violet ones. The real iodide of amylum is obtained by dissolving iodide of mercury in dilute muriatic acid by means of heat, precipitating it by tincture of iodine, and washing the precipitate with water. The author did not always see the violet colour ensue on mixing starch with pure tincture of iodine, but it appeared on adding a small quantity of nitric acid when a little gas, probably nitrous acid, was evolved; thus some oxygen must have united with the starch or the iodine: the former cannot be the case, because in mixing amylum and nitric acid, xyloidine is formed without disengagement of gas; perhaps a suboxide of iodine is formed. Iodide of starch has of course a less effect than a corresponding quantity of pure iodine. 2. *On the re-agents of iodine.* The author added to xyloidine (prepared by mixing starch-paste with concentrated nitric acid) an excess of nitric acid, and a few drops of neutral chromate of potash. Bichromate of potash is formed forthwith, and the fluid becomes yellow, and soon after bluish green. If a solution of iodine, or a liquid containing iodine, such as a drop of iodised urine is now added, a violet colour is immediately produced; this will soon disappear if the quantity be small, but will re-appear on repeating the process. By adding a larger quantity, a permanent blue liquid is formed; if you add a very large quantity of iodide of potassium, either no colour is formed or a reddish one, and the real blue only becomes apparent on the addition of nitric acid. Gas is also disengaged by pouring a saturated solution of iodine on the test. With it, iodine is even discovered in the native water of Hall, in artificial sea water, &c. Xyloidine is also a very sure test of iodine. (*Dr. Heller in Heller's Arch. f. phys. u. pathol. Chemie. u. Mikroskopie. I.* 1. 1844.)

Remarkable Effect of Emetics, as regards Increased Absorption, and in consequence, Removal of Pseudo-Structures. The author found in the scrotum of his son, six years of age, along the right spermatic cord, a tumour 2" long and ¾" thick, of uniform hardness, elastic and without pain. It had only shown itself three or four days previously. The surgeon who was called in, considered it to be sarcoma, and proposed to remove it by an operation. Before this, however, could be performed, the child was attacked with catarrhal affection of the respiratory organs, which induced the author to administer an emetic: (Tart. antim. gr. j. oxym. scillæ, et. aq. rub. idæ. aa. unc.) After the child had vomited several times, the tumour was found to be smaller by a third. The emetic was therefore repeated the next day, and the swelling again diminished. After this treatment had been continued for eight days, no traces of the tumour could be perceived. (*Dr. Fisher in Oesterr. Medic. Wochenschrift.*)

Drastic Effect of Narcissus Poeticus. (White Narcissus.) A person having stolen four bulbs of Narcissus, had them prepared with common onions as vegetables, and partook of them, with his wife. A quarter of an hour afterwards, both were seized with sickness, retching, burning pains in the stomach, delirium, syncope, cold perspiration, and a general trembling of the limbs. After taking lukewarm water, the wife vomited easily. When she had vomited several times, the above morbid phenomena diminished, and copious watery stools ensued with violent colic, giving relief. An oily emulsion with opium soon restored the patient. The husband had partaken more freely of the poisonous substance, and therefore the symptoms were more violent: lukewarm water did not cause vomiting, an emetic was administered in consequence (Ipecac. et vitriol. alb.) And even after abundant vomiting had ensued, giddiness, fainting, trembling, and coldness of the limbs continued during the greater part of the night, with a small trembling pulse. On the second day, symptoms of gastro-enteritis appeared, which rendered an antiphlogistic treatment necessary, and it was not until the fifth day that the patient was out of danger. (*Dr. Pfau of Lemberg, Ibidem.*)

PROGRESS OF IRISH MEDICAL SCIENCE.

(FROM OUR OWN CORRESPONDENT.)

Dublin, July 5th, 1845.

Case of Compound Fracture of the Leg, extending into the Ankle-joint; under the care of A. Ellis, Esq., F.R.C.S.I., one of the Surgeons to Jervis-street Hospital.

Michl. Craughwell, aged thirty, was brought to Jervis-street Hospital during the night of the first of July, having sustained a compound fracture of the tibia, about two inches above the ankle-joint, and extending into it; the fibula was broken at about four inches from its lower extremity. The wound over the tibia was considerably lacerated, involving the anterior tibial artery, the hæmorrhage from which—rather profuse—it had ineffectually been attempted to arrest by a medical gentleman, previous to the patient's admission. The vessel was now tied immediately, and no further hæmorrhage took place. His account of the accident was very unsatisfactory; he had been thrown, he said, from the box-seat of the vehicle which he had been driving, and on reaching the ground had twisted the foot of the injured limb: something more was evidently wanted to account for the lacerated condition of the wound with the protruded and comminuted state of the tibia. On examining the case at his morning visit, at nine o'clock, it appeared to Mr. Ellis, that from the nature and extent of the injury, amputation must necessarily be resorted to, and having requested a consultation of his colleagues at two o'clock, the immediate necessity of the operation was agreed to by all the surgeons of the hospital, and the limb was then removed by the double circular incision, at the usual distance below the spine of the tibia.

The condition of the patient was rather favourable to the performance of the operation, the shock from the accident having been trifling, his constitution vigorous, and a perfect willingness on his own part to submit to the advice of the surgeon. His progress since then has been most satisfactory; in an hour or two after the operation the pulse rose considerably, was full, bounding, with a remarkably corded feel, scarcely yielding to any amount of pressure, and leading to the impression that bloodletting would be called for. At his evening visit, however, Mr. Ellis found that those symptoms had considerably subsided, and that the amendment might reasonably be attributed to a pretty free oozing which had taken place from the stump since the last visit. On the night of the second instant, there was a good deal of restlessness, but this did not continue, or require any particular interference. An alkaline effervescing mixture was ordered, which was very grateful to the patient; and the bowels not having been moved for a day or two, an oily draught was administered. On the morning of the fifth, the stump was looking well and free from tension, the pulse ninety-six and soft. On examining the limb after its removal, fragments of the broken tibia were found in the substance of the muscles, and in addition to the fracture already alluded to, a portion of the articular extremity of the tibia was broken off; the bones of the tarsus were uninjured. Some clinical observations arising out of the case, to be delivered by Mr. Ellis on a future occasion, together with any further points of interest that may arise connected with it, will be referred to at another time.

Subcutaneous Section of the Hamstring Tendons; by J. Woodroffe, M.D., F.R.C.S.I., Surgeon to Jervis Street Hospital.

John Pilsworth, ætat. 13, admitted on the 6th May, with disease of the knee-joint of three years' standing; was brought by his friends in the expectation, that the limb would be amputated. His whole aspect presented the most marked scrofulous characters. From the appearance of the limb, and on an accurate examination of it, Dr. Woodroffe concluded, that the disease was chronic inflammation of the synovial membrane and inter-articular cartilages.

The flexor tendons were contracted to such a degree that the leg formed an acute angle with the thigh, but it was clear that no anchylosis existed, as the joint admitted of motion to the extent that the contracted tendons would allow, and this circumstance induced Dr. Woodroffe to try the effect of dividing them. Alterative doses of hyd. c. creta, and the application of ung. potassii iodid. to the knee, had the effect of improving the state of the joint, as well as the general health, and a subcutaneous section of all the flexor tendons was then made by Dr. Woodroffe, with a knife similar to that used by M. Guerin.

Extension gradually increased from day to day, as the joint permitted, was then practised, and the results have been most completely satisfactory, the limb being now in a perfectly extended state. The operation, it must be observed, was not followed by any inflammation of a serious nature.

Anchylosis of the joint in the extended position of the limb, may now be hoped to be effected, but Dr. Woodroffe seems to doubt much that an issue so favorable will follow, and dreads that progressive disease in the joint will ultimately lead to a necessity for amputation. A question now arises whether, though the constitutional taint be so strongly manifest, ulceration of the cartilages really exists; if not, is anchylosis an event to be sought for by keeping the limb in a constantly extended position?

Treatment of Chorea by the Use of Cannabis Indica.

This medicine has been administered with great success by Dr. Corrigan, in some cases of chorea, at the Richmond Hospital, the details of which are given in the *Hospital Gazette*. The subject of the first case was a girl, aged 10, in whom the muscles of the upper and lower half of the body, together with those of the tongue and face, were engaged. It had been of five weeks' standing on her ad-

mission, at which time she was ordered gtt. v. tr. can. Ind., ter in die; considerable amendment had taken place in eleven days, and the dose was then increased to gtt. xv., ter in die. This quantity she continued to take for a little more than five weeks, when she was discharged cured.

In a second case, that of a girl, aged 14, in whom the affection was confined to the left side of the body, it had commenced a month before admission, and after an oil draught, with turpentine, had been given, she was put upon doses of eight drops of the tincture three times a-day. The quantity was gradually increased to gtt. xxv. ter in die, the patient complaining of headache and lightness of the head after each dose. At a period of six weeks from the time of her admission, she was discharged cured.

A third case, occurring in a girl, aged 16, had been of ten years' standing at the time of her admission. She had been subjected to treatment at two hospitals previously, with slight amendment on each occasion. The affection here was more marked in the muscles of the arm than in those of the lower extremities, the patient being able to walk steadily. The affection in this case was ascribed to fright, but in neither of the foregoing ones could the patients attribute it to any particular cause. This girl took ten drops of the tincture, three times daily, and was discharged at the end of a month.

Dr. Corrigan also records the case of a lady, who had long suffered from severe neuralgia of the face, neck, and head, arising from cold. On several occasions she had found relief from the use of tonics, and the application of liniments.

From a very severe attack following influenza, Dr. Corrigan ordered gtt. xx. tr. can. Ind. ter die. The first dose, however, produced the following effects:—inability to swallow in half an hour after; could not keep her eyes open, though perfect consciousness of all that was passing around her remained; she then fell asleep for some hours, and on awaking felt a slight twitch in the left cheek. This occurred on the 19th of April last, since when she has been quite well.

In his observations on these cases, Dr. Corrigan goes into the question of the cause of chorea, and remarks, that from its greater frequency in females, it might be supposed to depend on the condition of the uterus, but that the disease is most often met with between the age of 7 and 14. He objects to its connection with cerebral derangement, because, he says, the subjects of the affection are remarkably intelligent, and the functions of the brain are undisturbed during the attack. It cannot, he considers, be traced to disorder of the digestive functions, as these are commonly in good condition, and accompanied sometimes with ravenous appetite—a feature that was present in the third case of chorea, alluded to above.

Viewing the negative and positive symptoms of the disease, then, he says, it may be looked on as a mere functional derangement of the motor nerves, either of the brain or spinal column, more frequently seen in females, because of the more excitable condition of the nervous system in them. Dr. Corrigan contrasts the effects of the Indian hemp with that of aconite, the action of the former being primarily on the motor nerves, its influence, he inclines to think, being transmitted along these to the sensorium and nerves of sensation, as in the case of tic douloureux, just alluded to in the lady, while the action of aconite is exactly the converse.

Speaking of the peculiar advantages of Indian hemp as a sedative, he assures us that even in over-doses it does not produce the dry tongue or derangement of the digestive organs, such as is seen to follow the use of opium; its effects on different individuals, however, he remarks are very variable, in the case of the lady for instance, twenty drops of the tincture caused temporary loss of power in almost all the muscles, followed by sleep, while a similar dose has been taken by other patients three times daily for weeks with impunity and advantage.

Dr. Corrigan thinks that in all cases ten drops may be given three times a day, increased after the third day to twenty or even thirty drops, but more than this he has never ventured to give; by mistake fifty drops were given instead of five to patients labouring under rheumatism and arthritic pains, for whom he had ordered the latter dose. In these cases the overdose produced severe headache, and what some of the patients described as white sight, but gave no relief to the pains.

Dr. Corrigan also alludes to the advantages derivable from the moderate use of electro-magnetism, when in the progress of treatment, the patient apparently on the point of recovery suddenly ceases to advance; this he has not known to occur in the treatment by Indian hemp, but frequently under the use of other remedies.

PROGRESS OF ENGLISH, ITALIAN, AND AMERICAN MEDICAL SCIENCE.

[The following are the principal articles of interest in two numbers of the *Lancet*.]

Utility of microscopic investigations.—Dr. Hughes Bennett, while treating of the importance of histology in diagnosis, observes that not long ago a man was admitted into the Royal Infirmary at Edinburgh, with complete paralysis of one side of the body, and partial paralysis on the other. He died, and on examining the brain to determine the nature of the lesion, nothing whatever could be seen, but on considering the symptoms, and the suddenness of the paralysis of both sides at once, Dr. H. Bennett was induced to re-examine the structure of the pons Varolii and medulla oblongata, and found in the former undoubted evidence of the existence of inflamed softening, combined with numerous exudation corpuscles. In another case, one of abscess in the arm, its approaching resolution was diagnosed from the appearance of fibrinous granules in the urine. M. Vogel, of Munich, in two cases, one of malignant disease, and the other of supposed malignant disease, availed himself of the aid of the microscope in forming his diagnosis with great advantage. In the first case, an ulcerated tumor near the angle of the jaw, the discharge, on examination, was found to consist, first of an amorphous matter, with blood corpuscles, and drops of fat; secondly, of crystals of cholesterine; and thirdly, of numerous cells, about one fiftieth of a millimeter in diameter, containing a large nucleus and a nucleolus. They were not flat, but globular. The character of these cells led him to pronounce the tumor malignant, an opinion which its increasing growth, the death of the individual, and a *post-mortem* examination confirmed. The other case was that of a woman, fifty years of age, of cachectic appearance, who had an ulcerated breast of six months standing. The ulcer was about an inch from the nipple, sunk deep into the substance of the organ, and about the size of a walnut. Its edges and the surrounding substance were firm and indurated. The glands in the axilla were slightly enlarged; the other breast healthy. It being requisite to ascertain the real character of this ulcer, before proceeding to an operation, an examination of the fluid upon the surface of the ulcer was made under the microscope, and exhibited, first, pus-cells, which on the addition of acetic acid, presented the usual granular nucleus. Secondly, there were several flux scales, presenting all the characters of pavement epithelium. Thirdly, there were cells of an elongated form, similar to those observed in granulations and cellular tissue in an early stage. From these circumstances it was diagnosed that the ulcer was not malignant, and it subsequently disappeared under the use of common applications.

Inflammation, ulceration, and induration of the cervix uteri.—Dr. J. H. Bennett states that when the inflammation and induration are the immediate or even proximate result of miscarriages, difficult labors, or of deep lacerations of the organ, there is frequently more or less inflammation of the uterus itself. If metritis is present, general antiphlogistic measures, such as bleeding from the arm, &c., may be indicated. So active a treatment, however, will seldom be found necessary. Generally speaking, the patients have been exhausted by flooding, by mucoso-purulent discharges, or by previous medication, and are not in a state to bear very energetic measures. Complete rest in bed, diluents, tepid hip-baths, emollient injections, poultices to the abdomen, and a few leeches to the hypogastric or iliac region, will nearly always subdue the general inflammation of the uterus in the course of a few days, so as to admit of examination with the speculum, which must not be attempted as long as the uterus itself is acutely inflamed. As soon, however, as the inflammatory symptoms have subsided, the examination should be made, as nothing will then so much tend completely to allay the irritation of the uterine system, as cauterisation of the ulcerated surface which, instead of exposing the patient to metritis, as has been asserted, seems to exercise the same beneficial effect over the surrounding uterine inflammation, that cauterization of an ulcer of the cornea exercises over ophthalmia. When the inflammation and induration affect the cervix only, general antiphlogistic treatment is scarcely ever required. Superficial cauterization, injections, rest, and light diet, will often cure the ulceration, and resolve the induration, the latter being generally occasioned and kept up by the former. This, however, only occurs when the nutrition of the engorged cervix has not been deeply modified by the subacute inflammation of which it has been the seat perhaps for months or even years. Not unfrequently, especially in very chronic cases, the hypertrophy only diminishes to a certain extent under this treatment, and even that very slowly, and then remains stationary, whether the ulceration heal or not. The cervix uteri continues to be the seat of general chronic inflammatory induration, and while this is the case, the patient cannot be said to be cured, as she still suffers from the uterine prolapsus, sensation of pelvic, heaviness, and bearing down, severe lumbar pains, constipation, vesical and rectal irritation, &c., and is liable to a relapse of the ulceration, with its attendant symptoms. As this chronic induration is exceedingly difficult of removal, the treatment must be directed from the commencement with the view to effect its cure. Complete rest is indispensable. In addition, if there be much hypogastric pain, large thin linseed poultices, frequently changed, should be applied to the part, and tepid hip-baths used twice a day. The cauterization of the ulcerated surface should be practised by the acid nitrate of mercury, or caustic potash. Emollient and astringent injections should also be thrown up. Attention must be paid at the same time to the bowels, and to the general health. If under this plan of treatment, the ulcer presents a more healthy appearance, and the hypertrophy of the neck appears rapidly to decrease, it may be continued, as it will probably prove quite sufficient to effect a cure. If this should not be the case however, other remedies must be had recourse to, the most efficacious being the application of leeches directly to the cervix uteri. Their application is easily effected, and they are most certainly extremely useful in subduing deep-seated chronic inflammation in this region. The following is the easiest way to apply them; after introducing an ordinarily conical speculum, wipe off the mucus which covers the cervix with a little lint or sponge, and then place the leeches in the interior of the speculum. Over its external orifice place a bit of linen, which depress with the finger into the speculum. In the concavity thus formed, place some lint or cotton, and then with the forceps push the whole towards the uterine neck. The linen carries the leeches before it, and presses them against the os uteri. On pulling out the linen and the lint, with which the speculum was plugged, in the course of about ten minutes, it will nearly always be found that all the leeches have taken. They generally fill well in this situation, and the flow of blood is often considerable after they have fallen. Six, eight, ten, or twelve leeches may be applied at once, according to the effect to be produced, and they should be re-applied (query, fresh ones used?) several times, at intervals of five, six, eight, or ten days, when necessary, until the desired effect is produced. The leech-punctures always heal readily. Their bite is not felt by the patient, unless they fix on the vagina, which they cannot do if the

speculum is properly introduced. The instrument must be held by the patient, or by the nurse, while the leeches are on. They generally fall off, but it is sometimes necessary to bring them away, after they have filled. If all these measures fail in causing resolution of the hypertrophied cervix, after trying the effects of time, and frictions with the hydriodate of potash and other solvents, the engorged cervix should be deeply cauterized either with the Vienna paste, or by the actual cautery. The eschar which forms in either case is much deeper than when the fluid caustics are used. The inflammation which accompanies its separation is also much more intense, and generally propagates itself to the entire cervix. The result is, that not only is the hypertrophied cervix diminished by the extent of the slough which separates, but that the healthy inflammation set up in the chronically indurated tissues gradually melts them as it were; so that often, on its subsiding, the hypertrophied cervix has regained its natural size. When this result is not obtained by the first cauterization, a second or third seldom fails to reduce the uterine neck to its normal dimensions. With the disappearance of the hypertrop,hy; also disappear the symptoms which it occasioned; the uterus returns of itself to the position which it naturally occupies in the pelvis, and the cure is really accomplished. The Vienna paste, which is composed of equal parts of quick-lime and hydrate of potassa, is applied to the uterine cervix in the following manner:—A large conical speculum must first be introduced, and the engorged cervix made to enter its orifice; or, should the cervix be too voluminous, the speculum must be firmly pressed on the part which it is intended to cauterize, care being taken not to enclose between the rim of the speculum and the cervix a fold of the vagina. About as much of the paste as would cover a fourpenny piece, must then be placed on a triangular piece of diachylon plaster, one end of which is inserted lightly in the cleft extremity of a small stick. The caustic paste is then carried by means of the stick, to the cervix, and applied to the centre of the part comprised by the orifice of the speculum. With the long forceps cotton is placed carefully all round the spot on which the caustic is applied, so as to protect the neighbouring parts completely; the stick is withdrawn, and the speculum is two-thirds filled with cotton or lint which is firmly pressed against the uterine neck. The speculum is then extracted, the cotton which fills it being forcibly pushed back in the vagina with the forceps, as it is pulled away, so that the vagina remains thoroughly plugged. If all this be carefully done, it is impossible for the caustic to fuse, and injure the vaginal parietes. In about fifteen or twenty minutes, the cotton or lint must be gradually withdrawn by means of a bivalve speculum, and an eschar of the size of a shilling, or rather larger, will be found where the caustic was applied. The vagina should then be washed out with a little tepid water, complete rest in bed enjoined, and emollient injections employed until the separation of the slough, which takes place from the sixth to the eighth or tenth day. This application of caustic, while it excites more inflammation than the more superficial, is rarely productive of metritis, or of inflammatory action to such an extent as to require local abstraction of blood. The application of the actual cautery is practised by M. Jobert de Lamballe, the neighbouring parts being protected by an ivory speculum. The application is said not to be productive of much pain, and to be very successful. We need scarcely remark that such practice must be confined to the continent; English women would not submit to it, and the surgeon who should be earnest in recommending it, would soon pay the penalty by the loss of his practice.

Obstetric action of opium and ergot of Rye.—Mr. Purefoy says that in cases of irregular and imperfect contraction of the uterus, he has experienced decidedly good effects from the employment of opium, whilst the ergot has been used under similar circumstances without any good effects.

Laceration of the knee-joints.—A chlorotic girl was admitted into the Leeds General Infirmary, with lacerated and penetrating wounds of both knee-joints from machine injury. There was a lacerated wound, about three inches long, outside the patella, penetrating into the joint, which would easily admit a finger under the patella. There was also a large contused and lacerated wound inside of the left knee, the integuments of which were much destroyed; the vastus internus muscle was much lacerated; the patella very much ground down, as if rasped by a rough file; there was an opening into the joint an inch and a half long, whence the synovia escaped, and mingled with the external coagulum. The wounds were dressed with dry lint, and coverd with oiled silk, and the patient kept perfectly quiet on her back. Opiates were exhibited at night for a few weeks, and general irritation kept down by appropriate medication. Suppuration ensued in a few days, and the wounds ultimately cicatrized. In consequence of the contraction of the integuments, the left leg could not be bent to a greater extent than to a right angle with the knee.

Bebeerine.—Mr. Tilley says this anti-periodic is isomeric with morphia. Its formula is:—

Found	C	72.22	35	72.11	calculated.
	H	6.62	40	6.77	
	N	4.30	2	4.82	
	O	17.02	6	16.30	

Its formula is therefore the same as that of morphia; its atomic weight is also the same. The number found as the atomic weight of the platinum compound of bebeerine is 6390.2; that of morphia (calculated) is 6255.7; a close approximation for bodies of such high atomic weights.

Pericarditis.—Dr. Taylor details the case of a young man previously in bad health, who was affected with acute rheumatism, the heart being healthy at the time of the attack, in whom pericarditis came on the day after the rheumatism ceased, accompanied by sharp pain in the left side, dyspnœa, irregularity of the pulse, and a systolic bellows murmur at the apex of the heart. The disease proved fatal in seventy-two hours. The examination of the body shewed recent adhesion of the pericardium everywhere but at the apex; the lower and back part of the left lung hepatized, and there were recent adhesions between the pleura of that side and the diaphragm. The morbid sound in the cardiac region is supposed by Dr. Taylor to have been a friction sound, closely resembling the mitral murmur. It was limited to the apex of the heart, which part alone of the pericardium was found to be free from adhesions at the post-mortem examination.

Puerperal fever.—Mr. Symonds divides this disease into three varieties, which he respectively designates the phlegmonous, the erysipelatous, and the remittent. The first of these, the puerperal metritis of writers, he treats by free general, and local bleeding, large bran poultices, free catharsis, and emesis, by means of calomel and colocynth, with tartar-emetic in the form of mixture, followed, after their action is fully established, by grey powder with ipecacuanha, with citrate and nitrate of potash and hydrocyanic acid or laurel water. If the pain and tenderness continue in spite of these measures, a blister of tolerable size may be applied to the hypogastric and umbilical regions. Mr. Symonds does not approve of Dr. Armstrong's plan of giving large doses of opium subsequent to the first bleeding. The second forms the true puerperal fever of writers, the erysipelatous, as Mr. Symonds and other practitioners have designated it, and is an exceedingly fatal disease. From some facts that have come to his knowledge, Mr. Symonds would be led to try the combined effects of bleeding, blistering, and quinine, given in small and quickly repeated doses. The third, the remittent, seems to be a compound of the other two forms, and presents a distinct remission and exacerbation once in the twenty-four hours. The *methodus medendi* is strictly, though moderately antiphlogistic. It seldom requires copious depletion, but leeches to the temples, and a blister to the neck may be needed to relieve pain in the head, after venesection. After an ipecacuan emetic, and a mercurial purgative, the grey powder with ipecacuanha, and the citrate and nitrate of potash with prussic acid may be relied on. The bowels must be attended to. When the febrile symptoms are subdued, quinine may be given with good effect.

Anterior obliquity of the uterus.—Dr. Pellegrini has published in the *Annali Universali di Medicina*, the particulars of a case in which labour was complicated by anterior obliquity of the uterus. According to Baudelocque, Velpeau, and others, anterior obliquity of the uterus never presents any obstacle to parturition, and is easily remedied. Baudelocque indeed affirms that the greatest inclination of this kind does not derange the mechanism of parturition, and that he has assisted at many labours which were concluded with facility, where the uterus was inclined so strongly forwards, that the abdomen fell like a sack on the knees. In October, 1840, Dr. Pellegrini was called to a woman who had been in labour for twelve hours—she was ætat. forty; had already borne four children, and for upwards of a year had been subject to gout. The abdomen formed a great sack, which hung down upon the thighs; and, although the woman was in the horizontal position, the fundus of the uterus touched the knees. The woman informed Dr. Pellegrini that her abdomen had begun to fall down in the fourth month, but that it caused her no alarm, for the same thing had occurred in her previous pregnancies without any bad effects. On the present occasion the midwife who had been with her had in vain attempted to replace the uterus: the contractions were strong, and directed from below upward; the membranes had been ruptured several hours. On vaginal examination the head was found presenting at the brim; the uterine orifice was widely dilated, directed to the vertebral column, and the posterior surface of the uterus had become the anterior. It was, of course, impossible for parturition to go on in this way, all endeavours to raise the uterus were unsuccessful, and when these attempts were prolonged, the patient was seized with convulsions. Dr. Pellegrini then thought proper to attempt turning: in this he succeeded, but the fœtus was dead, and the mother died four days afterwards of *metro-peritonitis*. Not even when the fœtus was extracted could the uterus be replaced, for a large mass of intestines immediately descended on the organ, and kept it still lying on the anterior surface of the thighs.

TRANSACTIONS OF LEARNED SOCIETIES.

Royal Medical and Chirurgical Society, June 24, 1845. Dr. Chambers, President, in the chair.

The following papers were read:—

On the Ophthalmia of Puerperal Women, by Robert Lee, M.D., F.R.S., &c.

After alluding to similar cases which have been recorded by Dr. M. Hall and Mr. Higginbottom, in the thirteenth, and by Mr. Arnott and himself in the fifteenth volume of the Transactions of this Society, the author relates two others which have since occurred to him, the details of which are given in the paper. He observes, that these cases present another opportunity of proving by dissection that the ophthalmia of puerperal women is the consequence of inflammation and suppuration of the uterine veins, or that there is a close relation between them; they also serve to confirm the accuracy of his former observations on uterine and crural phlebitis, and to demonstrate that in phlegmasia dolens, the inflammation commences in the uterine branches of the hypogastric veins, and extends from them into the iliac and femoral trunks of the affected side.

The particulars of a case of *pytyriasis nigra* were then detailed in a communication by Mr. Teevan. The patient was a young lady from Belfast, who, with the exception of the complaint under notice, was apparently in good health. The disease affected the forehead and eyelids, and commenced by a sensation of tension and heat, which was followed in a few minutes by the secretion of a blackish fluid, which gave the upper part of the face the appearance of having been daubed with Indian ink. The case was supposed to have been one of imposture, but Mr. Teevan convinced himself, by careful watching, that such was not

he case. The patient had, on her first arrival in town, consulted Dr. Chambers, and other medical men, before she placed herself under Mr. Teevan's care. She ultimately recovered from the disease, but, apparently, not in consequence of the treatment which was adopted, which was merely palliative.

Dr. Mayo enquired whether the catamenia were regular prior to the occurrence of the disease?

Mr. Teevan replied that they were not absolutely deficient, but they continued for a day or two only at a time. He had not examined into the character of the discharge himself, but had enquired particularly respecting it of the mother, who said there was not anything wrong about the secretion, as far as she could judge.

Dr. Chambers had seen the patient upon one or two occasions. When she first came under his notice, while the forehead was bedewed with this singular secretion, she looked as if belladonna had been smeared over the parts; as if, in fact, she had been under the care of an oculist, but on looking at it through a powerful microscope, it did not present a smooth or homogeneous appearance, but seemed as if the cuticle was broken up, like ichthyosis in miniature. He at first thought the patient was an impostor, but after the minute examination which he made, he was led to change his opinion.

Dr. Mayo thought, from the strange tricks that nature occasionally plays, that the disease might be looked upon as a singular instance of vicarious menstruation.

Dr. Chambers observed that Bateman had never seen a case of the disease, and had referred to Willan for its description. He, (Dr. Chambers) however, doubted very much whether Willan had ever seen it, as he said it was confined to children brought from the West Indies, and in them it appeared in the extremities only. This account did not at all tally with the particulars of the case under notice.

Dr. Williams asked the author of the paper whence he considered this black secretion was derived? whether it came from the sweat-glands, the sebaceous follicles, or where else it originated? It did not appear to resemble a modification of the cuticle, or ichthyosis, but was rather like a sebaceous secretion, such as is met with in various parts of the system. It resembled in appearance and character the pigmentum nigrum of the eye, and the fluid in melanosis. He thought it would be very interesting to know from what structure the exudation proceeded?

Mr. Teevan had watched the appearance of the exudation several times; he at first thought it resembled the blackness under the eyes of chlorotic females. It was, however, rather moist, and was removable by ablution. He was unable to answer Dr. Williams' question.

Dr. Chambers remarked that when this secretion was examined under the microscope, it presented the appearance of a thin black lamina, which had cracked as it dried. He could not detect any evidence of the presence of sebaceous follicles in it, and the skin was not in the least spotted after it had been removed. The girl looked very healthy when the eruption was out. She was rather good-looking, and had not any chlorotic indications about her.

Dr. Gregory inquired whether any local application had been used, and if so, what were the effects produced. He asked particularly whether any acids or alcalies had been applied, or whether a solution of nitrate of silver had been had recourse to?

Mr. Teevan replied that both the nitrate of silver and the decoction of oak-bark had been used, but without any effect in checking the exudation.

Dr. Chambers inquired if the surface of the skin beneath the exudation appeared to be healthy?

Mr. Teevan said, that the skin was perfectly healthy; neither Dr. Hodgkin, Dr. A. T. Thomson, nor himself, could detect any change in it whatever. No force was required for the removal of the exudation, either by oil, or soap and water. The appearance of the exudation was preceded by irritation, pain, and tension of the parts, and its frequent removal rendered the skin somewhat irritable.

Mr. Toynbee said it appeared from the examination of the secretion by means of the microscope, that it was composed of sebaceous matter, and pigmentum nigrum. Mr. Toynbee had had opportunities of examining small round jet-black masses developed upon the skin, and he had distinctly ascertained them to be made up of black pigment, granules, and sebaceous matter.

Dr. Chambers said that the black matter in the follicles of the face in acne punctata was often thought to be particles of dust, but it was also found in the follicles of the intestines.

Mr. Toynbee said, in favour of the opinion, that the black matter in these cases was composed of pigmentum nigrum, and not of extraneous matter, that it might be stated that the colouring granules were of an uniform size and shape.

The Society then adjourned till the commencement of the next session in November.

Royal Medico-Botanical Society, April 24th., 1845. H. Cope, Esq., jun., in the chair.

Dr. Cooke, the Professor of Toxicology, delivered a lecture on Stramonium.

As the datura stramonium has been much praised by many writers for its efficacy in relieving the paroxysms of asthma, and has been condemned by others as either inert or absolutely poisonous, it is a matter of importance to ascertain, if possible, the cases in which a drug, confessed by most of those who have employed it, to possess great powers, is likely to prove beneficial.

The powers of the drug may, perhaps, in some measure, be dependent on the manner in which it is employed. The forms usually adopted are the powdered leaves, gr. i.; the powdered seeds, gr. ½; the extract, gr. ¼; the tincture, m. xii.; and the herb or the capsule cut up and smoked.

The leaves and seeds only are in the "London Pharmacopœia;" the Dublin and Edinburgh Colleges admit the herb.

Much also depends, as in other vegetable medicines, upon the time of the year at which the plant is gathered: upon the care and knowledge employed in drying it for use, and upon the length of time which has passed between the gathering and administering it. The whole of the odour of the plant (probably dependent on a volatile oil) is dissipated by the process of drying, but the bitter taste (dependent on resinous matter) remains. The *herb* should be collected when the plant is in flower (July), be dried at a gentle heat, and by a current of dry warm air.

Presuming that these indications have been attended to, we may, perhaps, lay down the doctrine that experience has shown stramonium to be serviceable in cases of pure spasmodic asthma; and injurious in all cases attended with much congestion, or any inflammation. Stramonium is most particularly contra-indicated in persons of plethoric habit, tending to apoplexy. It is very seldom, too, that stramonium does more than afford temporary relief. Dr. Bree states, that he did not find a single case, out of eighty-three, permanently benefitted, but that twenty-four were injured by it. This was by smoking. From the rapid manner in which the effect is produced on the system by smoking any of the powerful narcotics, it seems highly probable that this mode of exhibiting stramonium is most likely to produce an immediate cessation of the urgent symptoms, as dyspnœa and pain about the chest (probably from muscular spasm), with consequent anxiety. It is probable, also, that the tincture or extract would be more likely, if regularly administered during the remission, to prevent the recurrence of other paroxysms. Stramonium has great power as an anodyne and anti-spasmodic; in fact, closely resembling belladonna in these properties.

The bad effects of stramonium are very serious, and unfortunately often come on suddenly, giving the remedy an appearance of being accumulative in its action. When improperly employed in asthma, it increases the dyspnœa, produces muscular tremblings, and temporary, or even permanent paralysis. In some cases it has produced syncope, which, from the frequent concomitance of disease in the circulatory system, has been fatal.

Stramonium has been much employed externally to relieve muscular and other pains, and with much success. The best mode of applying it is as a poultice.

The beneficial action of stramonium in asthma and other diseases is much increased by combination with diuretics. In this way also, the chances of its acting injuriously if administered in unfit cases, is greatly diminished. In many instances the smoked stramonium has been materially assisted by strong coffee taken internally.

NOTICES TO CORRESPONDENTS.

☞ *Subscribers who are in arrear since Midsummer, are requested obligingly to forward their remittances. By paying in advance for the year, a saving is effected to them, and much trouble about accounts spared to us. Our rule is to be paid in advance.*

M.R.C.S.—*We are not aware when Dr. James Johnson relinquished the* Quarterly Journal, *he so long conducted with so much credit to himself. We do not know the number of the* last *part that was published. M.R.C.S. has been quite misinformed.*

A.B.—*The secessions from the National Association are under a hundred, we believe; far less than could have been surmised in reference to any medical association so numerous. Supposing that there was even no organized opposition, yet with such conflicting opinions in the profession, and an association so plain spoken, the marvel is, that at so important juncture so united a body could be maintained. Nearly five thousand practitioners in continued communion with seventy-two representatives, is the best vote of confidence that could be passed. The additions to the Association weekly have been far greater than was required to compensate the losses.*

K. S. (Medicus) *is thanked—but his one subscription suffices.* £150 *instead of* £2000—*a reduction of about ninety-four per cent. on the* gentleman's *own estimate—is surely sufficient.*

Censor *recommends us to hold up to ridicule and censure the illicit habit of some medical practitioners, who exhibit in the windows of their shops or surgeries all the* insignia *of a disgusting and indecent species of practice. If the Council degrades surgeons—surgeons, it is affirmed, do it still more for themselves. Censor proceeds:—*

"No enemy can degrade them as they degrade themselves. Walking along C——n Street yesterday, I was attracted by a gaudy window, in which, among other delicacies, were exhibited copaiba capsules tastefully disposed in colored saucers, and a row of suspensory bandages hung on a line which extended the whole length of the window, each article ticketed with its name and value, (the rate of prices being, in most instances, lower by half than the sums charged by a Chemist.) From a brass plate on the private door of this bazaar of indecencies, I ascertained that the upper part of the house was used as a seminary for young ladies.—Yes, a seminary for young ladies—a garden for the cultivation of that freshness and purity of thought in which the crowning charm of the sex consists. It cannot, I presume, be questioned that, incomparably, the highest duty of a teacher's important vocation is to keep the youthful mind remote from all contaminating influences, unacquainted with every species of impurity; "Nil dictu fœdum visumque hæc limina tangat intra quæ puer est." But is this practicable where the door, through which pupils enter the school adjoins a shop-window ostentatiously dressed out with apparatus for males, who have been in company with diseased women of the town? The inquisitiveness of young girls is well known; and imagine a father hearing his daughter inquire the use of that long thing with tapes and a net-work bag which she had seen in C——n Street!

Dr. Rigg's *card has already received our censure. No member of a respectable profession should advertise after so tradesmanlike a fashion.*

Aspirant.—*No such observations have been published, except in our reports of Dr. Williams' Lectures. We cannot say in which number the subject is treated of by that Physician.*

Pamphilion.—*It is opposed to principle and etiquette, to prescribe through the pages of a medica*

periodical. A medical gentleman should be consulted.

A Pupil (Shaftesbury).—*The question in debate is a matter between the pupil and his master. If the master consents to the pupil's remaining two years of his time in town, and will deliver him up his indentures, on those conditions, there is no occasion for any further proof of his having completed his apprenticeship.*

An Old Subscriber.—*Medicine chests may be obtained of any wholesale druggist, and of an almost endless variety of quality, size and price.*

Our esteemed correspondent, Dr. Lewins, the late Censor of the Royal College of Physicians, Edinburgh, addresses us on the Seton case. Dr. Lewins severely reproaches The Times (*daily newspaper*) *for its impertinence in controverting the opinion of the jury expressed in Mr. Liston's favour. Dr. Lewins appeals to the authority of his " old friend" Mr. Liston's surgical repute, and to the support and concurrence of the two General Practitioners acting with him, as demonstrative proof of the impropriety of the* 'Times' *censure of his operation. He quotes Lord Robertson's flattering opinion of Mr. Liston's surgical skill and tact, and narrates, with great frankness, a case of his own, where, possibly for want of the operation, a patient died from hæmorrhage, the result of a rupture of a branch of the iliac artery. A quotation from Dr Armstrong is given, recommending surgeons to act for their patients' weal, careless of their own personal repute; and it is affirmed that if Seton had died without the operation, Liston would have equally been blamed, the poor surgeon thus standing before the public like the dupe before the thimble-rigger, " tails you lose, heads I win." Dr. Lewins finally gives the whole weight of his professional authority to the propriety of Mr. Liston's conduct in the Seton case.*

Nec temere nec timide *has written us a letter, agreeing pretty nearly with one in another column, on the approaching elections at the College of Surgeons. He insists on the Council maintaining their pledge of keeping a strict neutrality, and advises the Fellows to vote for the first able Fellow proposed. We have only one remark to make. Is the first* able *Fellow a just and sensible medical legislator? If so, will he do himself, and us, and the Fellows, the service of publishing his profession of faith? Let the Fellows support the Fellow who will advocate the largest ameliorations.*

—O.—*The communication on parasitic animalcules has already appeared in the* Medical Times.

A Student.—*We are now making arrangements for the appointment of arbitrators, who are to decide on the Students' Prize Reports. We propose the board to consist of two General Practitioners, one Physician, and one Surgeon.*

M.D.—*One of the cases recently reported from the practice of Dr. Rigby in our columns, exactly meets our correspondent's query. The recovery was a splendid tribute to that eminent physician's discernment and skill.*

M. R. C. S.—*The announcement respecting the decision of the Council to apply for a Supplementary Charter, is undoubtedly accurate. To what extent the proposed changes will reach nobody can surmise. The Council are about the most incomprehensible body of hesitating, shifting, and changing legislators known outside the walls of St. Stephens.*

Mr. Graham, the Registrar-General, has favoured us with a copy of a very convenient certificate book, to serve as a professional record of cases of death, with their causes. He proposes to supply a copy gratis to every qualified Practitioner. We need not urge on our brethren the immense advantages that would accrue to medical science if each gentleman would avail himself of Mr. Graham's suggestion, aided as it is by so handsome a facility.

We advise Scott *not to meddle with edge-tools.*

We consider A General Practitioner *to be certainly entitled to mileage when attending courts of law. The fee per diem differs in different courts.*

Lionel Lincoln *has mistaken our meaning. We meant him no unkindness.*

A HANDSOME PORTFOLIO *for holding the* "MEDICAL TIMES,"—*very desirable to those who would keep the numbers clean for binding, and easy of reference—may be had, by order of any Bookseller, or at the Office, price 5s.—An allowance is made to the trade.*

THE MEDICAL TIMES.

SATURDAY, JULY 12, 1845.

———Dum loquimur fugerit invida
Ætas. HORACE.

THE kaleidoscope is not more fruitful of changes than the brains of those who have charge of the Medical Bill. On Monday evening Sir Robert Peel, in announcing the Government measures, which were about to be postponed or abandoned, declared that the Physic and Surgery Bill was to be reprinted, with alterations, and then re-introduced: if not met with opposition, it was to be passed during the present session. The announcement was received, we are told, with peals of laughter, general and long-continued. We are not surprised at this uproar of Parliamentary cachinnation on a subject the laughers know as much about as the legislation of Kamschatka; but we are surprised that Sir James Graham should have hazarded, by unnecessary concessions, so natural and needless an expression of opinion. The enormous and countless difficulties surrounding Medical Legislation, in which, as in Alpine mountains, each high summit attained but gives a clearer view of those higher yet to be crossed; these difficulties of themselves were but too likely to fling any statesman grappling with them, in a false position in the eyes of those who, ignorant of the subject, could make no allowance for an incomplete or imperfect success. But when Sir James Graham, after obtaining that large professional support, which, while proving his measure good, secured its success, and guaranteed its popularity, flung away the victory that lay within his hands, and commenced a new series of negotiations, he committed himself to a course of procrastination, compromise, and concession, which could not ultimately fail of bringing him to defeat and ridicule. Out of an excess of 'obligingness, which, while esteeming, we cannot but condemn, the Minister has annihilated his own measure. He sought to have his Bill passed with—what cannot be ever had—the concurrence of every respectable party in the Profession; and to achieve his great object of giving this impossible satisfaction, it must be admitted that he has shown the utmost heedlessness of personal considerations, even in that House of Commons, where personal standing is almost everything. We dissent wholly from the *policy* pursued by the Minister: but it would be unfair and unhandsome in us to deny that he has shown a good faith and self-denying integrity in our service, that must for ever—successful or unsuccessful—commend him to our kindliest esteem and gratitude.

The Bill, with its new *alterations*—we wish we could be sure they were *emendations*—was to be submitted to Parliament this evening, (Thursday.) That it will be passed this session we have not the slightest hope. However good it may be, there will be opposition, and that opposition, however discreditable, will suffice at this late period of the session to prevent the measure passing through the trying ordeal of a House of Commons' Committee.

The great alteration in the proposed Bill, if we are correctly informed, refers to a second examination of the General Practitioners. The opposition of the College of Surgeons, strengthened by a partial cry by a few General Practitioners for a continued connection with that body, led to the proposal of a Board of Examiners, composed in equal parts of Physicians and Surgeons, which should give the General Practitioners with a second examination a second *title*. Sir James argued thus: "You seek a College for yourselves, governed on the representative principle. I give you that. A power of supervising your own curriculum free from all control. I give you that. The privilege of testing to the utmost point a candidate's competency to practice. That also I give you. But the College of Surgeons must not be ruined; and especially must it not be ruined when thousands of your body are willing for the further honor of its Surgical diploma to pay a second fee, and undergo a second examination. Instead of leaving their membership of the new College to their own option, and thus keeping up a double class of General Practitioners, let every General Practitioner after having his competency tested, undergo a further examination before the joint board, and be at once a Fellow of the College of General Practitioners, and Member of the College of Surgeons. The expense may be greater—the trouble increased—but the candidate will stand the better before society for the double ordeal, and the order of General Practitioners will have the dignity of the class maintained."

We own that this train of argument is sufficiently plausible—especially when there are so many who think that the members of the new College of General Practioners will stand the higher in public estimation for a continued connection with the College of Surgeons, but for ourselves we should be content as General Practitioners to stand or fall on the single examinations of the College at our own head. If men will have the vanity to wish for a second title, where one should suffice, it does not follow that the State should yield to their foible; but the truth is, the present arrangement is very cleverly adjusted to keep up an old Institution, by an adroit use of our weaknesses. Under the cover of a sham examination, attesting what has been already efficiently demonstrated, we get a title we covet, and the Old College gets a sum it cannot do without. The arrangement is evidently only a temporary one, and on that account, perhaps, the less to be deprecated; for till the New College make a high standing for itself, it will not be the worse for an arrangement, by which each of its Fellows becomes, *ipso facto*, a Member of the College of Surgeons.

It is supposed that under this plan the admission fee will be about thirty guineas; a portion, perhaps a fourth going to the support of the Hunterian Museum; another to be divided between the Physicians and Surgeons, and the remainder, probably a half, remaining with the College of General Practitioners.

At one o'clock this morning (Friday) nothing had been done with the Bill; it will, probably, be discussed to-night, or postponed to next session. In its present stage further criticism would be premature.

Accipiat sane mercedem sanguinis, et sic
Palleat, ut nudis pressit qui calcibus anguem.
JUVENAL

A dear-bought bargain all things duly weigh'd,
For which a thrice concocted blood is paid,
With looks as wan as his, who, in the brake
At unawares has trod upon a snake.
DRYDEN.

IT will be remembered that our disquisition upon tea was suggested whilst treating of its particular use by medical students. We intended to mention it only incidentally, as a means very commonly employed, amongst others, for the prevention of sleep; but a belief that a more enlarged treatise would be void neither of amusement nor of edifi-

cation, led us into a digression which we hope again to make when we come to discourse upon other popular subjects, such as alcoholic stimulants, tobacco, &c.. It remains for us at present, however, to say what are the further means resorted to by students whose ambition prompts in them the desire to be watchful over much.

We are told by Seneca, that Parrhasius, the famous painter of Ephesus, bought one very old man out of the Olynthian captives, whom Philip of Macedon conveyed home for sale, and when he had the poor fellow safely, beat and variously tortured him, that he might, from the agony and writhing of the sufferer, the better express the figure and features of a Prometheus, he was about to paint. Our intention towards our readers is the exact opposite of the wicked old painter's towards his slave. We mean, as aforetime, to represent the miseries which people have voluntarily entailed upon themselves, to the end that, by these examples, and the suggestions of our own judgment, we may the better obviate the continuance and propagation of injurious practices. We are much attached to the didactic, or preceptorial style; it furnishes the best opportunity possible for making one's subject lofty and one's self important, but we are not quite so certain as to the usefulness of it. It might do all very well for the philosophers of old, who took up so much time in learning and digesting matters, that when they *did* venture upon an *ipse dixit*, their opinion might be considered little short of immaculate. Plutarch says that the life of a vestal virgin, was divided into three portions: in the first, she learned the duties of her profession; in the second, she practised them, and in the third she taught them to others. That was just what the philosophers did—a man was never permitted even to ask a question until he had for a certain length of time listened in the academy, nor was he, until long after this, permitted to express an opinion about anything. Thou best, busiest, and wisest of all bees, from whose gatherings we have culled many a drop of honey, sweeter and more nutritive than any now hived—dear old Plato, the crack "bee of the Athenians," would that thy injunctions prevailed just now! What an amount of foolery that we hear uttered, by great men and little ones, would have been checked, had Plato's suggestion been made "lynch law." What a treat to snip a bit off the tongue of a scolding wife who defied kindness to cure her—what a *burning* example to mark a blackguard's lip with a brand of infamy, and make him careful of his words for ever—what a luxury to pitch-plaster the mouth of a brawler, eloquent of humbug and bring him to the enviable state of thinking, often before he ventured to speak at all! The thought may seem a cruel one in these days of oratory, when a man *gets* more, and *shines* more, by what he says, than by what he does—but we *like* the thought, and we luxuriate over it as we think; if it were only a law applicable on the instant, how many mouths we should have the happiness of stopping! But it is not so, and we are sorry for it, for there is a certain amount of parrotising we are all compelled to hear, evade it as we will. Now, as the philosophic maxim of old is not the maxim of to-day, ourselves, in common with others, some sensible, and some silly, have not learnt the most desirable trick of "hearing all you can and saying nothing." That everlasting tea-table gossip, Cowper, brought silence into disrepute—genius of the faculty, mark his poem with charcoal—by saying this twaddle:

> The man I trust, if shy to me,
> Shall find me as reserved as he,
> No counterfeit or pleading
> Shall win my confidence again—
> I will by no means entertain
> A spy in my proceeding.

Loquacity set in, in double earnest, on the strength of that bit of versification, which, in our opinion, did far more to establish the abominable practice, than the eloquent poetry of Shakspere, which tells us that

> ——— Silence is only commendable
> In a neat's tongue dried.

"Intercommunicableness intercommunicable," like railroad shares, is chiefly the fashionable and marketable commodity in the times we live in—all are talkers, few are thinkers—the didactic, properly so called, has gone out of fashion, because there are none fit to bestow, and few willing to receive it, and ourselves, consequently, *cum multis aliis*, take the more epigrammatic road of fact, anecdote, and narration. These things require no thinking about, you have only to see, hear, or read them, and off they go again from yourself with as much consequence as if you were their original. And many a man, permit us to tell you, worthy readers of these observations, has got a fair reputation, by dealing out second-hand, such *materiel* as is contained on the pages you are now perusing.

After what we have said in favor of Plato, and his great maxim, we should be sorry to say anything calculated to lessen his weight with posterity, but whilst we have stated the *necessity* of our anecdotical and matter of fact style, as compared with the didactic, we consider it due to ourselves and our system, to say that this style is not without its advantages. Some writers affirm that example is everything, and precept nothing—or as we once heard it classically rendered by an old man-midwife at a temperance meeting in a methodist chapel, "a grain of fact's worth a pound of theory." It will scarcely be believed that such a man could write a book—but he did write one, and precious rubbish, as might be supposed, was stuffed into it. Another proof of the advantage that would follow the stopping of people's pens, as well as their mouths. This fellow may be taken in illustration of the influence of example—his was a bad one, and mischief resulted from it, for it became contagious. Horace rightly says

> Decipit exemplare vitiis imitabile.

Had it been exposed with propriety, more would have been inclined to flee than to follow it, and so, though in itself a vice, it would have produced a virtuous issue. This is the great beauty and service of narrative—"to show virtue her own feature, scorn her own image, and the very age and body of the time, his form and pressure." It is easily conveyed, is as easily received, and rarely fails of endurance. Philosophical precepts require philosophical heads to listen to them, and perhaps as we *now* live and learn, St. Augustine might with some truth apply his great comparison of the two chief sources of instruction—"Magis intuebantur quid fecerat Jupiter, quam quid docuit Plato."

Our immediate object then,—having determined upon the means wherewith to execute it—is to inveigh against over study, its plans, and some of the sources of its promotion, and to illustrate its evils by instances of hearsay or observation. The burden of our subject lies with that unhappy class of men, intellectual Dandos, who have such voracious appetites for mental food, and such capacities for stowing it, that not satisfied with gluttonising all day long, they will actually, like the ass with his bundle of hay, chew all night at it. And when nature fails them, and its "sweet restorer" would fain curtain their eyelids with something comfortable, they summon one Cerberus or another to keep it away, as though, instead of like a friend, it came "as a thief in the night." We mentioned some of these, who have done despite to themselves in this wise by the profuse imbibition of green tea; the next class we have to exhibit are those who perpetrate a like misdemeanor by the local use of cold water. The hydropathists say that, like Captain Dalgetty's mulled ale, it is "the best shoeing-horn known for drawing on a sound sleep"; and we also say, that it is as efficacious as a group of furies, for driving off one. Aretæus tells us of people having *ingentes et crebras vigilias*, great and frequent watchings, lasting for a month or a year at a time. Hercules de Saxonia affirms that he heard his mother swear she had not slept for seven months together. Trincavellius knew a man who was awake for fifty days, and Schenkius one who never slumbered for two years! these are extraordinary enough, but our own experience goes far beyond them, for we knew of instances in which, after a certain use of cold water to keep their eyes open, the operation has been so effectual with the victims, that they have never slept again, except "that sleep which knows no waking." A foolish experiment and a fatal issue! And all this for the sake of amassing a load of information that is as useless and burdensome as the accumulated gold of the miser, which being hidden, brings no interest with it. The wealth of this man is of less use to him than it would be to another, who, though he had it more sparingly, would employ it to some good end; and the stored learning of the other, being unwieldly in its mightiness, is just as serviceable as the musty materials of a lumber room, upon which obscurity has set its seal for ever. It was well observed by Dr. Kippis, that, such men have so may volumes in their heads there is not room for their brains to move: or as Rhasis rightly hath it, *multa appetunt, pauca digerunt*, they eat more than they can digest. A favourite writer of fiction speaks of a bass singer who could go so low nobody could hear him; and so it is with your great scholars, they are so profound you cannot fathom them, or at least nothing short of a diver of Delos could hope to do it. And little do they think how great a mischief is the heritage of their toil. Ficinus rightly says, "other men look to their tools; a painter will wash his pencils; a smith will look to his hammer, anvil and forge; a husbandman will mend his plough irons, and grind his hatchet if it be dull; a falkner or huntsman will have an especial care of his hawks, hounds, horses, and dogs; a musician will string and unstring his lute; only scholars neglect that instrument (the brain and spirits I mean) which they daily use, by which they range over all the world, and which by much study, is consumed."

THE TESTIMONIAL TO THE MEDICAL TIMES.

In the course of our editorial experience, nothing has more gratified us personally than the amiable zeal with which our friends have demonstrated their kindness to us on the occasion of Mr. Wakley's late legal *escapade*. Insignificant as was the event itself, kindliness to us seems to have given it importance: and our friends have felt stimulated to exertions, which prove to us the double truth—how largely our labours have been appreciated, and how much of help we can count on, should any real demand for it arise. Already, within about a week, nearly two-thirds of the damages allotted by the jury as the utmost amount at

which they could appraise the character of an M.P. and Coroner, have been subscribed!

Now, that the expression of feeling in our favour has been so prompt, so promising, and so satisfactory, it may not be unbecoming in us briefly to say, that whatever the amount that may be subscribed, we propose to return it wholly to the Profession. We believe that every particle of our animadversions on the famous or infamous public men, who seek to lead or mislead the Medical Profession, tended at whatever hazard to ourselves, to serve the good cause; but published by *us*, we are anything but desirous to place on others our responsibility. While gratified, therefore, on the one hand with the homage paid to the *public* and *disinterested* quality of our opposition to unprincipled and designing wrong, we take leave, on the other, respectfully to propose, that the subscriptions of the Profession on this occasion shall be used, not to defray the costs of our service in boldly analyzing political unprincipledness, but for the higher purpose of founding prizes for the advancement of medical science. If we may judge from the subscriptions already received in so exceedingly short a time, there is a very reasonable prospect that the total amount will not be less than £500, and may amount to £1000. In either of these cases, we will found a perpetual *biennial prize*, open to the competition of every British and Irish Medical Practitioner; the successful candidate receiving, in one case, the sum of Fifty Pounds — in the other, a Hundred. We would thus perpetuate, in a way serviceable to the Profession, the memory of an action which was meant to be as destructive as it turned out to be insignificant, and which was incurred on our side solely in a desire to present the world with a Profession no longer discredited with unhappy and damaging associations.

HOUSE OF COMMONS.

Several very important motions were announced for last night (Thursday.)

First, we have Sir James Graham for going into Committee on the two Medical Bills—the Physic and Surgery Bill, and that for granting certain Charters.

Secondly, we have the Lunatic Asylums' Bill, (of Ireland), which is to go into Committee.

Thirdly, we have Mr. Muntz's motion, which will be put as an amendment, that before the House go into Committee, the latter be instructed to consider the propriety of writing prescriptions, &c. in plain English.

Fourthly, we have Mr. Wakley's old ill-fated motion for an Enquiry into the late Charter.

Fifthly, comes Mr. Shaw's motion for reserving a certain Professional Appointment to the Irish College of Physicians.

And finally, we have Mr. Murphy proposing the following amendments:—

22. Mr. Serjeant Murphy,—In Committee on the Physic and Surgery Bill, to move the following Amendments:

In Clause 2, line 11, of page 3. after the word "England," that the words "one general Practitioner to be chosen by the Council of the College of General Practitioners in Medicine, Surgery, and Midwifery of Ireland," be added.

And in Clause 3, line 27, after the word "England," that the words "the general Practitioner chosen on behalf of the said College of General Practitioners in Medicine, Surgery, and Midwifery of Ireland," be added.

And in Clause 4, line 10, page 4, after the word "Majesty," that the words "and upon every vacancy made upon the same Council by the member chosen on behalf of the General Practitioners of Ireland, the Council of the Royal College of General Practitioners in Medicine, Surgery, and Midwifery of Ireland shall choose another General Practitioner to supply such vacancy, subject to the approval of her Majesty," be added.

And that in Clause 14, line 15, after the word "Act," the words "shall be qualified to enrol and" shall be omitted.

And in the same Clause, line 17, after the word "England," the words "or of the Royal College of General Practitioners in Medicine, Surgery, and Midwifery of Ireland," be added;

And in the same Clause, line 23, after the word "Royal," that the words "Colleges of Physicians and Surgeons in Ireland" be omitted, and the words "College of General Practitioners in Medicine, Surgery and Midwifery of Ireland," be substituted.

And in Clause 17, line 43, after the word "England," that the words "or by the Royal College of General Practitioners in Medicine, Surgery, and Midwifery of Ireland," be added.

And in Clause 20, page 9, line 2, after the word "Scotland," that the words "or Ireland" be omitted.

And in the same Clause, line 4, that after the word "Surgeons," the words "of Scotland" be added.

And in the same Clause, line 4, that the words "in that part of the United Kingdom in which he shall have received his letters testimonial," shall be omitted, and the words "and every person registered in Ireland as a General Practitioner shall be required to enrol himself as a Fellow of the Royal College of General Practitioners of Ireland," be added.

And that in Clause 33, page 14, line 7, the words "and no further or otherwise" be omitted; and in line 23, of same Clause, that the words "and no further or otherwise" be omitted.

THE LATE FATAL DUEL AT GOSPORT.

(To the Editor of the Medical Times.)

SIR,—I find in your journal of last week some criticisms by "an old Army Surgeon" on a letter of mine that appeared in the *Times* of the 21st of June, with respect to the medical treatment of the late Mr. Seton. I beg to make a few remarks on those criticisms. Your correspondent says, first of all, that the letter of "M.D." is "below criticism," which conclusion he venturesomely arrives at, because "the writer has not the least idea of the difference between a *wounded artery* and an aneurism!"—an assumption, sir, as futile and untrue as it is bold and unwarrantable. I plead altogether ignorant of this charge. In my letter to the *Times* I took it for granted that every medical man would assume it as a fact, on the evidence *already* given, that the aneurismal tumour for which Mr. Liston hoped to find a remedy in tying the external iliac, was what is termed *a false aneurism, arising from a lacerated artery caused by a pistol shot.* This seemed to me so self-evident, that I went at once to the question of the propriety or impropriety of Mr. Liston operating for *such* an aneurism, without conceiving it possible for any one to be simple or wilful enough to construe my intended omission into ignorance, or be so unjust as to accuse me of not knowing a wounded artery from an aneurism.

In regard to the other criticisms on my letter, they are far too ridiculous and *irrelevant* to deserve particular notice, as are, indeed, most of those against the other medical men. And when I find this "old army surgeon" and "*civil* surgeon and physician" falsifying his adversary's position, unceremoniously assuming others for that adversary which are not acknowledged, and then advancing some of his own, as wild as they are inapplicable, to argue illogically on the whole, I begin to think he is indeed *too old* to put forth an argument at all; and that Government would have done much better to have superannuated their "*old* army surgeon" before he ever vainly dreamt of being a *civil* one, and pensioned off services which, if ever performed at all, must have been when he was *not* old. Besides, while he—this *old surgeon* of army and civil experience—querulously disapproves of whatever was done for Mr. Seton, he suggests nothing that might have been done! He would have us suppose, I imagine, that under the mask of his silence, there was a wisdom that passeth knowledge.

I am, Sir,
Your obedient servant,
M. D.

Southsea, July 8th, 1845.

THE LAW OF LIBEL.

As to actions for defamation and libel, we have notions upon the subject certainly not very favourable to adventures like Mr. Phillips; notions that must be more popular than they are, before the freedom of the press will be anything more than an empty name. We, though happily ourselves less involved in such matters than any other who ever addressed the public daily for so many years, must give it as the result of a long and attentive observation, that, in 19 cases out of 20, libel actions are most sordid attempts at robbery; that in 19 cases out of 20, the plaintiff, to speak plainly *lies* knowingly, when he asserts injury; that the judge and jury, when they ratify his assertion by awarding damages, we will not say *lie*, for that would be disrespectful, but "affirm the "thing that is not," to borrow the euphemism of the Houyhnhnms. We have reserved a twentieth for cases in which the plaintiff in a libel action is not a conscious liar, when he complains that he has sustained an injury, and we think the exception of a twentieth exceedingly liberal, though we include in it a great majority, who, excited by timidity, or inflamed by passion, believe that they have sustained injury, which really they have not sustained. Few, indeed, are the cases in which a libel can really injure any one in a country like this, where for one organ open to asperse, there are hundreds available for wiping off the aspersion.

* * * * * * *

There are cases, no doubt, in which libel actions offer the only remedy for wrong—these cases occur when men are charged with offences, so grave, so foul, or of such a nature as that they cannot vindicate themselves with sufficient promptitude to escape an interval of suffering—or again where the rabble are excited to assault them. Our readers will recollect the peals of "thunder" in "the Monster" case, and the exhortations to the use of "brickbats and bludgeons," as examples of those detestable classes of libels, which no good man would grieve to see expiated by the cord or the cat-o'-nine-tails. A libel, however, which can be answered by the next day's newspaper, in this age of newspapers, of rail-roads to carry them, and of free newspaper postage, can inflict no real injury, and is in fact no libel, and the press will not be free until judges and juries find out this truth. Lord Campbell's bill has done a great deal for the press, but more remains to be done—even if judges and juries improve their view—for the defence of a libel action is a very serious matter even when successful.

Pickpocket plaintiffs will always be forthcoming to raise money upon threats. The proper remedy is to give no costs save in case of grave damage.—*Standard.*

MR. ROSS ON MEDICAL REFORM.

Just before going to press we have received a long communication from Mr. Ross, having peculiar reference to the topics in question during the present week. From the lateness of the hour, we must do ourselves the violence of at once abstracting the letter with large extracts of the more telling *morceaux*, rather than publishing it at length next week, when much of its interest would have expired.

Mr. Ross, addressing Mr. Wakley, M.P., begins

with a reference to the influence he for some time possessed with a certain part of the Profession, and to the proportionate responsibility which attached to his conduct in the present crisis. He suggests that now is to be tested the wisdom of the confidence that has been placed in him, and the mischief or utility of his advocacy. Mr. R. confesses to have been Mr. W.'s coadjutor for eighteen months. During that time, when he could not approve, he was silent, or contented himself with a protest against the vacillation he condemned. He continues:—

Silence, however, is now a crime—a hardy opponent must be hardily answered; the crisis has arrived when neutrality would be dishonour, and a passive acquiescence in wrong a shameful cowardice. Besides, your own intentions and objects have been discreetly concealed until the last few weeks; for I must confess, that I have often listened to you with the view of ascertaining what might really be your ultimate aims, and although I have been exceedingly amused by your ingenious special pleading, your cautious frankness, artful resentment, and salient dexterity of argumentation, yet my curiosity has never been gratified. Your eloquence has much of the Will-o'-the-Wisp character, which, instead of being a beacon to a safe road and happy home, insidiously leads the traveller into a morass. You might have indulged in these peculiarities without censure, if you had employed them to win over your opponents to a just cause, to avoid giving offence to your friends, and to combine in one great and overwhelming body all the moral and intellectual power of the Profession. *This you have not done*; you have striven to make and unmake—to unite and divide—to spread dissension, and foster prejudices, but you have not succeeded. Your conduct is ours to scrutinize—*your motives are your own.*

I believe, Sir, that you are anxious to stand well in the opinion of the Profession; the consciousness of their disapprobation has cost you many a bitter reflection, and plunged you into acts which later experience has caused you to repent. Repentance is not, however, always followed by reformation, and by a curious perversity of mind, you have determined to continue in a career, which, knowing to be wrong, you hope your obstinacy may seem to justify. It is this kind of infatuation which ruins most men of strong will and hard intellect.

Your fault, Sir, has been to anticipate the judgment of your professional brethren, to deem your own edicts the oracles of wisdom, to exact an abject submission—a servile obsequiousness to your opinion; and if, after all your tactics, you could not succeed in enthralling the professional mind, to give the rein to your passions, and strive by every art, power, and means, to blast the labours of the Profession, and accomplish your individual projects. The truth must be spoken, however unpalatable it may seem; it is no time now to quibble about terms, or to think one thing, and express another. You are, in your own person, one of our best authorities for freedom of opinion, and liberty of speech.

If, Sir, you had not made that unfortunate congratulatory oration on the introduction of the second Medical Bill by Sir James Graham, I apprehend that your tactics would have materially changed. You found that the Profession did not support you; what you applauded, they condemned; this conviction incited you to redeem your position, and on the introduction of the third Bill, you as violently censured as you had before earnestly approved. You were again at fault—the Profession did not support you; it was a grievous mistake, and I have no doubt you have lived to regret it.

Consistency, Sir, was sacrificed on all these occasions, and with that your political character was seriously damaged. Men who have been successful in life are apt to rely upon their own infallibility with too much complacency; they think that the tide of events will ultimately carry public opinion in their favor. If they are consistent, this is usually the case, but if uncertain and capricious, seldom; and it must not be forgotten, *that a recusant to his faith may be forgiven in youth, but never in mature age.* The down-hill of life is often, to men of expediency, the down-hill of reputation. The juggler who commands our admiration while he conceals the trick, is despised when his arts are revealed. Time unmasks all mysteries; it lays bare every heart, and very few can sustain the vivid light which it throws upon their deepest recesses.

Ever since you have been a medical reformer, you have advocated a reform of the College of Surgeons; it has been your hobby; you have cherished it as an act of retaliation for the personal insults which, in early life, you received from the Council. The recollection of these insults has worn its channel deeper and deeper the more you have dwelt upon them. You have clung to this hope of revenge with an unrelaxing tenacity; it is the osier-twig that binds together all your other projects; it gives an air of sincerity to your schemes, an earnestness to your zeal, a vehemence to your denunciations—it is the very Benjamin of your heart—your master-passion! You have been, indeed, consistent on this point. But you forget, that all the members of the Profession are not animated by the same bitterness of feeling. They judge more calmly, and with more unbiassed minds: times and circumstances have changed—new forces have been brought into play—new principles are at work—nobler objects are opening upon us, and we must now act, not upon the musty records and faded remembrances of years, but upon the pressing realities of the present hour.

Even yet, Sir, you may regain the confidence of your professional brethren, by assisting to acquire for them an Incorporation on the representative principle, and to secure the passing of a bill in Parliament, by which they may be endowed with an efficient power in the State, with a Court of Appeal against corporate mismanagement—a ready access to Parliament—a more extended protection in the practice of the Profession, and a closer approximation, if not a perfect realization of those great principles which you have ever supported—the unity and indivisibility of medical science, and the uniformity of medical education.

These boons are offered to us in the Bill about to be re-introduced to the House of Commons;—*will you be foremost in rejecting them*—in repudiating all your past professions, and in sacrificing a great cause, that you may enjoy the indulgence of quibbling upon trifles, and congratulating yourself upon the achievement of an unworthy victory? What do you conceive will be your position with the Profession after such a procedure? Can you deceive yourself for a single moment, by supposing that you can wheedle from the General Practitioners the lowest murmur of approbation? In my opinion, you are now in a most precarious position; your character is at stake; you are standing before the tribunal of public opinion; out of your own mouth you will be judged; henceforth, it will be decided whether you shall be considered the friend or enemy of the General Practitioner! Let not pride, ambition, nor the instinct of retaliation blind your better judgment, and prompt you to pursue a line of conduct which, as sure as you live, will redound to your *dishonour*! I bear you no ill-will—I have admired your talents—I have respected you for the good you have done; but the welfare of my Profession, and my own sense of right, outweigh every other consideration.

Mr. Ross now twits Mr. Wakley on his league with the monopolists against the General Practitioners, and proceeds:—

Your present conduct, Sir, in Parliament, will be a lesson of warning to the Profession. Defeated out of the House, in your attempts to overthrow the National Association, you have agitated in the House with the assumption of a moral force do you not possess. Professing to be the representative of the General Practitioners, you have neglected their wishes, and are the most resolute opponent to their interests.

The petitions you have recently presented against the Bill are in reality of no value, since most, if not all of them, were sent to you for presentation under false impressions, as is proved by the desertion of the movement, by whose instrumentality these petitions were drawn up, and I apprehend that no man is better aware than yourself, that these petitions were the result rather of a temporary agitation of public feeling, than of a deliberate judgment. Nevertheless, they will serve the purpose intended, and I must do you the credit to say, that you have sagaciously and opportunely employed them. I anticipate, that by the time this letter is published, you will have declared your sentiments. I shall be glad to find, that my fears have been vain, and that the Hon. Member for Finsbury has been the advocate of right, justice, and professional independence. Nothing could be more grateful to me—nothing more honorable to yourself.

ASSOCIATION OF SURGEON DENTISTS.

To the Editor of the Medical Times.

SIR.—Having repeatedly called attention to the present anomalous position of the Dentists of this country, and regretting that there still exists a supineness on the subject, I venture once more to address those interested, through the medium of your excellent Paper, particularly as Parliament is now legislating on Medical and Surgical affairs.

The Surgeon Dentists remind me of the position of Teachers. Having alluded to Teachers, I may briefly explain the reason:—Any persons in this country may become school-masters or mistresses, whether qualified or not. This is not the case on the Continent; there they must not only be examined by an Educational Board as to their literary capacity, but also as to their moral respectability; and then they receive a license, which in case of subsequent delinquency is cancelled, &c. the application I leave like the poet's to the imagination of the Reader. They may be *professionally* qualified, or they may not, but the public have not means to discriminate, inasmuch as there is no *legal* qualification, by which the man of science can be distinguished from the Charlatan: and though the former may in time obtain his proper *status*, and his science and skill may gain him confidence, yet without some diploma or license he might have the chagrin to be confounded with "the wonderful-cement-men," or with those teeth manufacturers who *modestly* profess to rival, if not surpass, dame Nature, by their own equally wonderful discoveries.

The importance however of Dental Surgery is now recognised by the most eminent men, as not only useful for preserving the symmetry of the mouth—preventing deformities which would otherwise destroy the expression of this beautiful feature,—giving at the same time the power of proper accentuation, but as useful in aiding the physician in his diagnosis of some of the most distressing maladies which embitter life, it being now ascertained that often *cerebral* and *spinal* irritation is primarily induced by diseased teeth—the local irritation in the *alveoli*, &c., sympathetically affecting the important vital organs previously mentioned.

Will then a knowledge of fitting artificial teeth be deemed a sufficient qualification for a dental practitioner? Or ought a man who is merely a successful tooth extractor, or a good stopper of teeth, to be alone entitled to practise as a surgeon dentist! I think not. It being evident that to practise with honor and utility, a man should possess a knowledge of general anatomy, physiology, and pathology, and these should be *specially* acquired so as to obtain an internal knowledge of the mouth, its nerves, muscles, glands, &c., &c. And though many dentists have these acquirements, yet be it remembered that those who have not such qualifications are still called "Surgeon Dentists," and as I have previously said, *until the public learn by experience the difference, they cannot ascertain that there is any legal qualification to distinguish them.*

Let then, some of the most influential metropolitan Dentists bestir themselves, and petition the legislature, that they may add a clause to the proposed New Bill, to render it imperative that all future dentists shall undergo an examination as

to their professional qualifications, and then to have a license to practise dental surgery: and though the law would be *prospective*, yet some of the respectable men now practising (who are not members of the College of Surgeons) would also submit to such a test, and thus confirm their right, being treated with confidence. I may add, that a friend of the writer, who had been in practice many years in this country, and obtained extensive patronage from his skill and knowledge of the profession of dentistry, removed with his family to———, a town in Germany, where he was obliged to go through a prescribed course of study, and undergo a searching examination, before he was permitted to extract even a tooth. Why should foreign states show greater regard for the health of the community, than our own government. If however the legislature will not protect this useful department of practice, let the dentists unite (as in America) and form themselves into an "Association of Surgeon Dentists," appointing a board of Examiners to examine future candidates for membership, as in this same way the College of Surgeons was first instituted.

I am Sir,
Yours very respectfully,
J. L. LEVISON.

14, Devonshire Place, Brighton,
June 20th, 1845.

THE COUNCIL OF THE COLLEGE OF SURGEONS AND THE APPROACHING ELECTION OF COUNCILLORS.

To the Editor of the Medical Times.

SIR,—It will, doubtless, be in your recollection that upon the occasion of the election of Councillors last year, a great many *hard words* were bandied about between the names of several of the members of the Council, which probably were, in some measure, justified by the cajolery and deceit practised by this not particularly popular, nor indeed immaculate, body.

I am anxious, in common with the Fellows of the College generally, that this year, whatever hard names may be called, the Fellows shall clearly understand whether the Council do or do not intend to interfere in the approaching election of of Councillors; and for this purpose make this appeal through your impartial and widely circulated columns. I have heard that the Council have agreed among themselves,that they will *not interfere*, but in the face of any belief of such a report there is to be placed the conduct of the Council last year; when, it will be recollected, some of the Council asserted that such a resolution had been come to, and others as positively denied it. We can only place the respective credibility of the Council against each other, the result of which I suspect will be something like the following.—

$$\text{Mr. L.} \times \text{Mr. S.} = x + y.$$
$$\text{Mr. M.} \times \text{Mr. C.} = x + y.$$

The one sum deducted from the other = 0, about the amount of credit to be attached to these *gentlemen* of the Council.

However, my principal purpose in addressing you, Sir, is, that the matter this time, may be clearly and explicitly understood—let us have no jugglery, let all be above board and plain sailing. Do not let the wishes of the Fellows be contravened by the wily machinations, and dark intrigues of the Machiavels of the Council Board. It is manifest that such a body, if only from its number, must have very great influence, and will generally be able, from the want of unity, and concerted action among the Fellows, to control in almost any manner they please, the election of the Councillors. If they exerted this influence in a fair and legitimate manner, none would be less inclined to cavil at it than myself; but when I see the most unprincipled means had recourse to, to keep particular men out of the Council,—when I see a gentleman belonging to a hospital at the eastern end of the town, spitefully, maliciously, and combinedly excluded,—when I also see other gentlemen, eminent for their talents, and highly-esteemed by their professional brethren,—I need hardly say that I refer to Sir Stephen Hammick, Mr. Gossett and Mr. Macilwain, men who have distinguished themselves by their discoveries and contributions to surgical science,—when, I repeat, I see such men kept out of the Council for the sake of favouring the surgeon of some particular hospital, I cannot but condemn the influence exercised by the Council as most prejudicial to the interests and well being of the profession at large.

If any such resolution, as that which I have referred to has been agreed upon by the Council, let it be publicly known; let every Fellow be made distinctly aware that the members of the Council will neither nominate, vote for, nor take any part in the approaching election of Councillors. For unless "the taking no part" has reference likewise to the *not voting*, it is nothing more than a feint on the part of the Council, which will throw some off their guard, and enable others in the secrets of the Council to take advantage of the unpreparedness of the Fellows. But even supposing that they shall honestly and *bona fide* have arrived at such a resolution, neither to vote or take any part in the election, it is somewhat late in the day, considering that it is generally known that the Council are united in support of one man, for whom the Council have been canvassed; nay more, and for whom the Council have been canvassing for the last six or nine months; in fact, ever since the resignation of Mr. Thomas was in the hands of ———.

This certainly, I think, you will admit, is the strangest way in the world for a body to abstain from taking any part in the matter, and cannot fail of putting the matter in an altogether different light to that in which the Council would have it appear. In spite then of a "God bless you!" Joseph Surface-like member of the Council, having "pinned" the Council down to this resolution, as I hear he boasts of having done, it is the sheerest piece of humbug that this successful diplomatist of the Council has ever been guilty of, and that is saying a great deal—for we know the man!

I would then caution the Fellows against being taken in by this juggling of the Council.

Then be these juggling fiends no more believed
Who keep the word of promise to the ear,
And break it to the hope.

Let the Fellows meet, and unite in support of those gentlemen whom they wish to be on the Council, and who will better represent their opinions than those now in. And this consideration is the more important from the probability of the "physic and surgery bill" being thrown over board. For a reform of the Council and the Charter, they will, in such case, have to trust to the Council themselves. It is well known that there is a minority of them in favor of a more extended admission to the Fellowship, not excluding Practitioners in Midwifery from the Council, and of reforming the abuses entailed upon the profession by their Charter. Let then the Fellows add to this minority by filling up the three vacancies with men pledged to these views, and it cannot fail of remedying the defects of the Charter, a cure for which they have sought of Sir James Graham in vain.

I should think it was scarcely necessary to point out to the Fellows how Messrs. Welbank, Scott, Cutler, have altogether falsified the opinion which was entertained of their sentiments previously to the election; it will at all events be unnecessary to inform the Fellows that the strongest upholders of the exclusive character of their body corporate, and the fiercest opponents of any relaxation of the Charter, have been these three gentlemen. These men must then be expelled and new blood infused in the Council by the election of the three Senior Fellows; viz., Stephen Hammick, Mr. Gosset, Mr. Macilwain, who were so unjustly excluded last year, all of whom are pledged to support the more liberal views entertained by a minority of the Council,—added to which it is but fair to these gentlemen,as likewise to Mr. Lloyd and Mr. Kingdon,who were passed over with them last year, that the Fellows should know, that according to a bye-law of the Council, if they are passed over a second time, they will be for ever after ineligible. This being of course the object aimed at by the Council, let the Fellows frustrate this as far as possible by the election of the three senior gentlemen, which will give the others an opportunity of again coming forward; and the profession will fulfil the double object of doing justice to meritorious men, and of reforming the profession without the intervention of Parliament.

I am, Sir,
Your obedient Servant,
AN ODD "FELLOW."

Tuesday, July 8, 1845.

[A public meeting of Fellows should at once be held.—ED.]

INSPISSATED AND DESICCATED OX-GALL.

Mr. G. W. Blanch, of Vassall Place, Brixton Road, calls our attention to some improvements in the preparation of ox-gall for medicinal purposes, a remedy, the use of which was revived by some excellent papers by Dr. Clay of Manchester, in the *Medical Times*. Mr. Blanch states that when given in the *inspissated* form, the patients complained loudly of the disgust it caused,as well as the griping pains which frequently followed, and the utter impossibility of keeping the pills separate. By using it in a *desiccated* state,these evils are avoided, and in numerous cases of torpidity, or disorder of the liver, Mr. Blanch has prescribed its administration with the best effects. In a few cases only, a diarrhœa resembling that frequently occurring in spring and autumn was observed, but this may be attributed to the too long continuance of the remedy, and ceased on its being omitted.

BOOKS RECEIVED.

REMARKS ON PHYSICIANS, SURGEONS, DRUGGISTS, AND QUACKS, ADDRESSED TO MEMBERS OF PARLIAMENT, THE MEDICAL PROFESSION, AND THE PEOPLE OF GREAT BRITAIN. By SURGEON SNIPE. London: Highley.

This pamphlet gives a very forcible sketch of the mischief of quackery. The author demonstrates it to be what our legislators are not aware of seemingly—a social calamity. We have a very good analysis of the education and uses of the different classes in the profession, with judicious suggestions on the improvements now pretty generally advocated. The pamphlet abounds in that sterling unsophisticated good sense for which the general practitioner of the present day is celebrated.

PRACTICAL FACTS IN CHEMISTRY. London: Simpkin, Marshall, and Co.

This book is offered by Mr. Ede, of Dorking, as a key to his "Portable Laboratories." For beginners in Chemistry it will be found serviceable as an elementary treatise of a a very practical character; and there are suggestions in it which may save a good deal of time and money to experimentalists much further advanced.

THE CHYMICAL DELECTUS. Second Edition. By George Cox. Published by the Author.

This "Delectus" is published with the same object as the work last noticed. It is smaller, not illustrated, and altogether more unpretending; it is, however, well written, and fulfils its object of serving as companion to "Mr. Cox's Cabinet Laboratories."

MESMERISM AND ITS OPPONENTS; with a Narrative of Cases, by GEORGE SANDBY, Jun., Vicar of Flixton. London: Longman, Brown, and Co.

This a very sensible book, written in a very classical style, on a subject which more than any others, perhaps, tempts to exaggeration, both in partisans and opponents. With various opinions in which we do not agree with the author, his book has not ceased at any time during perusal to command for him our esteem. All the interesting problems of mesmerism come under discussion, and are handled with good sense, and a very tolerant temper.

THE IRISH WATERING PLACES, THEIR CLIMATE, SCENERY, AND ACCOMODATION. By ALEXANDER KNOX, M.D. Dublin: Curry and Co.

A most pains-taking and creditable book, on a very useful and interesting subject. To the invalid seeking a change of residence, and looking for it towards Ireland, Dr. Knox's summary will be invaluable. Of two of the Irish mineral springs, most celebrated for the "certainty and speed of their cures," it is reported that one derived all its virtues from a communication with a neighbouring tan-yard, and

the ether to the daily addition of a hundred weight of Glauber's salts!

Observations of the Growth and Irregularities of Children's Teeth. By W. H. Mortimer, Surgeon Dentist. Highley.

A popular book, but written in a more scientific spirit than most similar works. There is much sound sense in the writer; and we see in his little work many of the ingredients which, with due addition, would fill up a gap, too long left open, and constitute a sensible and disinterested popular Instructor on the Teeth.

The Manual of Pharmacy for the Student of Veterinary Medicine. By W. J. T. Merton, Lecturer on Veterinary Materia Medica. Third Edition.

The "Manual" has been already very favourably noticed by us, and its arrival at a third edition only leaves us the duty of congratulating the judicious author on his well-merited success.

Seven Lectures on Somnambulism, translated from the German of Dr. Arnold Wrenholt. By J. C. Colquhoun, Esq., Advocate, author of "Isis Revelata." Adam and Charles Black, Edinburgh.

A very extraordinary work, full of profound thought, and very elegantly translated.

Ozone.—At a meeting of the Chemical Society a paper, containing the details of a series of experiments on azone by Mr. Williamson was read. The name ozone was given by Schönlein to the substance which occasions the peculiar smell possessed by oxygen gas when produced by the voltaic decomposition of water, and he has made it the subject of much ingenious speculation, concluding that it is a new elementary body, and that it is derived from the decomposition of nitrogen, supposed to be of a compound nature. The last of these opinions, however, has already been disproved by Marignac, who demonstrated that the ozone odour was produced by the decomposition of water free from nitrogen. Mr. Williamson's experiments go to prove that ozone is a compound body, and that one of its elements is hydrogen; for having excluded the last element from any other source, by obtaining the oxygen gas with ozone from the decomposition of a salt of copper—a process in which no hydrogen is generated, and passing the oxygen over metallic copper which had been reduced by carbonic oxide gas, a sensible formation of water always resulted. The bleaching power of ozone shows it to be a peroxide; and it must, therefore, be a higher oxide of hydrogen than water, although not the peroxide of hydrogen of Thenard, which is not volatile like ozone, but inodorous and fixed. Mr. Williamson finds also that the substance produced by the action of phosphorus on air is different from ozone, and that its effect, observed by Schönbein in decomposing iodide of potassium and liberating iodine, is the result of the joint action of phosphoric acid and free oxygen upon a solution of that salt.

The frequent spontaneous cure of pulmonary phthisis.—Dr. Hughes Bennett, at a meeting of the Medico-Chirurgical Society of Edinburgh, observed that if the cicatrices and concretions occasionally met with in the lungs, indicate the previous existence of tubercle, it must heal spontaneously much more frequently than is generally supposed. Of seventy-three bodies he had examined since last November, he found puckerings or concretions in the lungs in twenty-eight. Of these, puckerings existed, with indurations alone, in twelve; with cretaceous or calcareous concretion in sixteen. They occurred in the right lung seven times, in the left lung twice, and in both lugs nineteen times. In three individuals the age was 18; between this age and forty there were six, and after that epoch of life, nineteen. That these lesions were really proofs of cured tubercle was proved by numerous facts, and by the circumstance that every pathologist since the days of Laennec had considered this to be established. Hitherto, however, these lesions had been considered as occurring very seldom. The author, on the other hand, considered that his observations, combined with those made by Roger and Boudet in Paris, sufficiently proved that they occurred in proportion of from one-third to one-half of all the individuals who die after the age of 40. He then pointed out that neither the chemical nor structural composition of tubercle, nor the nature of the action which accompanies its deposition, are in any way opposed to the facts revealed in morbid anatomy. As regards the question whether tubercle was or was not an inflammatory product, its solution would depend on what was meant by inflammation. If the essential phenomena of that process consists of an exudation of blood-plasma, as he believed, then tubercle must be considered of inflammatory origin. Tubercle consists of granules and imperfect cells; the products of inflammation are composed of granules and perfect cells. Both are formed by the exudation of blood-plasma. If it undergo transformation into perfect organisms, it constitutes what pathologists have in some cases called the results of inflammation; in others, different kinds of tumours. If there transformations are worsted, or rendered imperfect, it forms what has been called tubercle, or scrofulous deposits He also observed, that as empirical means for accomplishing a cure had notoriously failed, perhaps a study of the method in which nature operates might be more successful. The progressive march of tubercular depositions towards a cure was then minutely described. If when a cavern is formed, the further deposition of fresh tubercle could be checked, its walls unite, or close upon the contents, which undergo various transformations, and thus a cicatrix is produced. These cicatrices present differences according as the cavity is superficial or deep-seated. Sometimes no traces of tubercle are found, and they consist of dense fibrous tissue, surrounded by indurated pulmonary parenchyma, rendered dark grey or black by increased pigmentary deposit. More generally hardened tubercle is found, or cretaceous and calcareous concretions, which are frequently surrounded by a cyst. These may remain in the lung without producing irritation, and are sometimes expectorated with the sputa. It was evident that this process would readily take place, if the pathological causes inducing the disease could be overcome. These were—first, a morbid state of the blood, the result of imperfect nutrition; second, local inflammation, by means of which an unhealthy exudation is poured out, that assumes the form of tubercular or scrofulous matter. The imperfect nutrition depended upon, first, an excess of oxygen in the system, which combines rapidly with the tissues to produce waste, and to occasion acidity in the alimentary canal; and second, an excess of nitrogenised or albuminous, and a deficiency of carbonised or oleaginous matters in the chyle, blood, and tissues generally; the liver, the great emunctory of fatty and carbonised matter, being excepted. The indications for *treatment*, therefore, are—first, to overcome the dyspepsia and acidity in the alimentary canal; second, to furnish the material necessary for the formation of a healthy chyme; and, third, to combat the local inflammation. The dyspepsia and vomiting were often to be relieved by naphtha, when all other remedies had failed. Dr. Bennett ascribed the boasted good effects of this remedy to its power in allaying the irritability of the stomach, and thus enabling the patient to take nourishment. The imperfect nutrition was best to be overcome by an easily-digestible and nutritious diet,—milk, substances abounding in oleginous rather than albuminous principles, and an equable warm climate, whereby, in conjunction with the diet, the excess of oxygen in the system may be diminished. In carrying out this second indication, the author strongly recommended cod-liver oil as a most valuable remedy. The local inflammation must be combated by topical blood-letting, in an early stage, and later by counter-irritants. In conclusion, Dr. Bennett expressed the hope, that whatever opinion might be held with respect to the value of the indications and treatment proposed, the facts he had brought forward would induce renewed trial, directed to the *curative*, rather than the mere palliative treatment now so prevalent.

GOSSIP AND NEWS OF THE WEEK.

Royal College of Surgeons.—Gentlemen admitted Members on Friday, the 21st June, 1845:—J. S. Drury, R. S. Thornley, T. Horsfall, L. Llewellyn, H. Young, J. E. Palmer, H. A. Oldfield. Monday, June 23rd:—C. E. G. La Motte, W. Price, C. Mulholland, W. Ewing, W. Bainbridge, P. E. Downs, W. T. Black, D. M'Bride, J. Orred, J. Jones, J. E. Hamilton. Friday, June 27th:—W. A. Eves, W. Wilkinson, S. M. Frost, T. B. W. Buckler, J. W. Slight, J. H. Elliott, A. Haviland, W. W. Moore, W. Preston, F. J. Freeland, T. F. Dybale, J. H. Jerrard, M. Teevan. Monday, June 30th:—C. Goodwin, W. G. King, G. J. Langford, T. A. O'Flaherty, T. M. Parrott, R. Blackie, R. D. Blucke, H. S. Colston. Friday, July 4th:—W. Arthur, N. H. Littleton, W. T. Wilson, H. A. Warburton, E. Warburton, W Scott, L. Kerans, C. K. Webb, L. Leslie, A. May

Apothecaries' Hall.—Gentlemen admitted Licentiates, 3rd May, 1845:—James Gilmour, James Robertson, Samuel Bertie Cator Barrott, William Lane.

The Journal of Veracity.—In a somewhat impudent contemporary the statement is made, that no meeting had been held for the Testimonial to the *Medical Times*, and that the gentlemen proposing the resolutions disclaimed the responsibility. The following documents, signed almost at the instant, shew the historical faith that may be attached to a public instructor.—*From the Proprietors of the Crown and Anchor Tavern*:—"Crown and Anchor Tavern, July 7th, 1845—I certify, that on Monday, the 23rd of June, a meeting of medical gentlemen, open to all members of the Medical Profession (*no instructions to refuse admittance to any*), was held at the above tavern. I have reason to believe, that the meeting was to take steps in reference to a testimonial to the Editor of the *Medical Times*,—James Carter." *From the undersigned gentlemen*:—"We, the undersigned, hereby affirm, that certain resolutions advertised in connection with the recent action against the *Medical Times*, were passed and published with our sanction and approval,—R. Knox, Wm. B. Costello, G. D. Dermott, H. J. M'Dougall, John Ryan." Perhaps the following very gratifying letter of Dr. Weatherhead will complete this *expose* of a foolish calumny:—"63, Guildford Street, Russell Square, 24th June, 1845—My dear Sir,—I am obliged to go to Hampstead on particular business; but as I regard this proceeding of Mr. Wakley as degrading and contemptible, as respects the money appraisement of the value of his character, I cheerfully offer my mite (£3. 3s.) in part payment of the valuation.—Very faithfully yours, G. Hume Weatherhead.—To W. B. Costello, M.D.

No. 304 **SUMMARY.** JULY 19

CLINICAL LECTURES ON MEDICINE.

Delivered at the Meath Hospital.

By ROBERT J. GRAVES, M.D., M.R.I.A., &c.

GENTLEMEN,—We have a considerable number of cases at present under treatment, none of which are of permanent importance, but each possessing a degree of circumstantial interest sufficient to entitle them to a few passing observations. The first is that of Eliza Hawkins, who was attacked on the 8th of March with rigors, headache, and nausea, and was admitted on the 10th with well-marked erysipelas of the inner and back part of the leg. The erysipelatous blush commenced immediately above the instep, and extended over the inner surface and calf of the leg, being terminated both above and below by a well defined outline. The inflamed part was extremely tender and painful, and the pain with some degree of tenderness extended along the inner surface of the thigh as far as the groin, evidently in the course of the lymphatics. She had completely lost the power of the limb; she could neither raise the whole limb nor could she bend the leg on the thigh, nor the thigh on the pelvis She had some fever, but her pulse was rather soft, and she perspired all over her body, except over and to some distance round the parts affected with erysipelas. There was no infiltration of the subcutaneous cellular tissue

The first thing to be observed with respect to this case is, that the erysipelatous surface and a considerable portion of the skin immediately round it felt hot, perfectly dry, and rather harsh, while the rest of the body was covered with a copious perspiration. Now this affection of the circumjacent skin would seem to prove, that though it had not as yet been attacked with erysipelas, still that its functions were already deranged It would appear, also, that this change in the condition of the skin precedes the spread of erysipelas by means of redness, pain, and increased heat. The next point deserving of notice is, that in this case the lymphatics appeared to be more or less engaged, for the pain extended up along the thigh in the direction of their course, and as far as the chain of glands which is situated below Poupart's ligament. This is not an unfrequent occurrence in erysipelas of the leg, and I think it very possible that in such cases the superficial veins might also become involved in the inflammation.[1]

One of the most remarkable circumstances, however, connected with the present case is the extraordinary impairment of the muscular functions of the limb. Here we have a mere superficial disease, confined to the skin, and not engaging the subcutaneous cellular tissue, much less the fascia or muscles, and yet the muscular power of the limb is so deranged, that she cannot move it in any direction. The same thing occurs in another superficial disease, phlegmasia dolens. The patient has frequently the leg as perfectly paralysed as if she laboured under complete paraplegia. How are we to explain this? You are not to suppose that there is here any affection of the spinal cord, any disease of the bones or ligaments of the vertebral canal, of the great nerves or of their sheaths. I have in two lectures, delivered at the Meath Hospital, endeavoured to impress upon the class what is the true source and origin of the paralysis observed in this woman's case, and have shown that it arises from a cause operating, not on the nervous centres, but on their sentient extremities. The present case affords a clear and beautiful example of the fact, that from an affection occupying only a certain portion of the leg, and wholly superficial, a person may have the muscles, not only of the calf, but also of the thigh, rendered completely powerless. As an illustration of paralysis produced by an affection of the sentient extremities of the cutaneous nerves, this case is highly interesting.

The next case to which I shall briefly draw your attention is that of Eliza Highland. Since her accouchement, which took place five months ago, this woman has had no return of the catamenia. Her belly is greatly enlarged, particularly over the region of the uterus, and on making an examination we found the swelling dull on percussion and without any feeling of fluctuation. It is plain, therefore, that it can be neither tympanitis nor ascites, and that the tumour must be caused by the presence of a solid substance. There is, however, no tenderness on pressure, and as she labours under an acute affection of much more importance, we have not made such satisfactory examination as would enable us to give a distinct opinion on the nature of the case. All we can say at present is that the uterus is deranged in its functions, and that there is probably some extensive organic disease of that viscus or some of its appendages On her admission she had, in addition to the affections which I have already mentioned, loss of power of both the lower extremities, and delirium tremens. I may observe with respect to the paraplegia, that it does not seem to be connected with any affection of the spinal marrow or its various investments. It is very probable that it depends on the abdominal affection, whatever it may be. I have shewn that paraplegia may depend upon enteritis. Mr. Stanley has adduced several cases to prove that it may be connected with an affection of the kidneys, and his correspondent Mr. Hunt has shewn that it may be produced by disease of the uterus.

The lady whose case I mentioned in a preceding lecture, and who had become paraplegic after an attack of enteritis, continued paraplegic for about seven months, when she evidently began to get better; she is now quite well. Two issues at each side of the spine seem to have served her materially Since my lecture was published, Mr. Carmichael observed a case of paraplegia following acute enteritis; it occurred in the person of the surgeon of an hussar regiment quartered in Dublin. I am anxious to record this as an additional example of a species of paraplegia, which I was the first to describe and explain.

In this case we had to take into consideration, not only the abdominal affection and the paraplegia, but also what was of much more importance, the delirium tremens. The patient, who is a butcher's wife, has been an habitual toper, and, having the means of gratifying her propensity for intoxicating liquors, she has indulged without restraint, particularly for the last three weeks, drinking not only during the day, but also whenever she awoke at night. When admitted her pulse was 120, soft and compressible, her skin moist, and her bowels confined. She had been for many days and nights without sleep, and raved incessantly; her delirium running, as is usual in such cases, chiefly on matters connected with her business. From the state of her tongue, which was inclined to be red and dry, I was doubtful at first whether I should give opium in full doses, or whether I should give it in moderate quantity, and combined with tartar emetic I prescribed two ounces of the tartar emetic solution, with six ounces of the camphor mixture, and one drachm of laudanum; two table-spoonfuls to be taken every second hour. The second dose caused vomiting, but there was no change in her symptoms. Next day I increased the quantity of laudanum to two drachms, and she got some sleep To-day I intend to give the opium alone, and I have no doubt but that it will succeed. When once you have been able to procure sleep, the cure of delirium tremens is an easy matter.

A young woman, named Ann Trotter, was admitted on the 2nd of March, labouring under syphilis. She has an eruption on her forehead and temples of three weeks' standing; she has also sore throat, which commenced about the time of her eruption. There is a good deal of constitutional irritation present, her bowels are inclined to be costive, and she sleeps badly at night. Like most cases of secondary syphilis in young and vigorous persons, the eruption was preceded by a considerable constitutional disturbance; she had rigors, thirst, heat of skin, pains in different parts of the body—in fact, all the symptoms of high inflammatory fever With respect to the character of the eruption, it does not seem to belong exactly to the class of papulæ, for the spots are much larger and less acuminated. They are not, however, either pustular or vesicular. Some would be inclined to call them tubercular, but the appearance of their apices are against this appellation. They are large elevated papular blotches, about the size of a pea, are surrounded with an inflamed base, and have a small point of vesication or pustulation at the apex These papular blotches (I do not know of a more significant expression) last for a long time, and then disappear gradually by process of desquamation, which commences at the apex, and, if the disease be not removed, they are then succeeded by a fresh crop.

In referring to this case, I purpose merely to direct your attention to some points connected with treatment. On the day after her admission, she was bled to fourteen ounces, and took a purgative mixture composed of infusion of senna, sulphate of magnesia, and tartar emetic. This operated freely on her bowels, and, with the bleeding, contributed materially to remove febrile excitement. The next day we applied twelve leeches to the throat, and she was ordered to take a tablespoonful of the following mixture every second hour:—℞. Aquæ acetatis ammoniæ ℥ vj, Liquoris antimonii tartarizati ʒ iij, Acetatis morphiæ, gr. ss. My object here was to keep up the antiphlogistic plan in a mild degree, by acting on the skin with antimonials, and to relieve constitutional irritation

[1] In a recent lecture I spoke briefly of the pathology of *phlegmasia dolens*. I forgot, however, to revert to a most interesting and original case detailed by me in a former course of lectures published in this journal, and in which phlegmasia dolens suddenly attacked and destroyed the eye. The importance of this case has been appreciated by *Müller* in his account of the progress of the medical sciences in 1833

and produce sleep by means of the acetate of morphia. On the day following we found that she had slept much better than usual, her skin was soft and moist, and her fever nearly gone. We continued, however, the use of the diaphoretic mixture until the fifth day, when we commenced a different mode of treatment.

In all cases of secondary syphilis, where the eruption has been ushered in by symptoms of high constitutional excitement, you should commence your treatment by a mixture of the antiphlogistic with the diaphoretic plan; you should bleed, leech, give cooling purgatives, and afterwards prescribe antimonials. These, with low diet, continued for four, seven, or ten days, as the exigency of the case may demand, will remove all febrile excitement, and prepare the patient for the use of mercury. On the fifth day, then, after having subdued the symptoms of febrile disturbance, we gave this young woman three grains of blue pill, and half a grain of calomel three times a-day. It is now only seven days since we commenced the administration of mercury, and yet any one who has attended to the case cannot but be struck with the remarkable improvement in her symptoms. The eruption has nearly faded away, her throat is healing rapidly, she has no pains or feverishness, and her aspect is quite that of a person rapidly convalescing. By making venesection, purgatives, and diaphoretics precede the use of mercury, you attain two important points; you cure the disease in a shorter time and with less mercury. There are two points connected with the treatment of such cases which cannot be too well impressed upon your attention; they are themselves extremely simple, and looked upon by some as unimportant, but they tend most materially to facilitate the cure of syphilis; they enable you to prescribe a smaller quantity of mercury, and prevent it from (as it is termed) going astray. One of these is, that you should, if possible, keep the patient in bed while he is under treatment. I do not mean that you should shut him up in a warm room, and keep him covered up with half a dozen blankets, but merely that you should keep him in bed as much as possible. I know very well that John Hunter and others say that mercury will counteract the syphilitic virus, and cure the disease under any circumstances, and that the patient may, while taking it, walk about and pursue his ordinary avocations. This may be true in many instances; but I am fully convinced that where a patient remains in bed, there is always less danger of the mercury going astray: nor have I known such patients to be attacked a few weeks afterwards with periostitis, as those frequently are who have taken mercury at a time when they were in the habit of going out, and following their usual employments. The next point refers to diet. Now, when you have to treat a case of this kind, do not allow your patient to take meat and wine; the less he uses of these articles the better. I am aware that restrictions in diet have been considered useless, and that it has been stated, that the man who eats a good dinner and drinks a pint of wine will be cured just as soon as the most abstinent. This I have found, by experience, to be a false assertion; and I am inclined to think that the advantages to be derived from an attention to diet have been too much overlooked. I seldom permit my patients to take anything but slops, and I would advise you to do the same. These are the principles which should guide you in the treatment of secondary syphilitic eruptions, preceded by fever, and accompanied by more or less constitutional excitement. Keep your patient, if possible, in bed; confine him to low diet; commence his treatment with bleeding and purgatives, followed by antimonials; and when you have subdued the inflammatory and irritative part of the complaint by these measures, then proceed to attack its specific nature with mercury.

A case of syphilis was admitted into the male chronic ward about three days ago, which exhibits some peculiarities deserving of the most attentive consideration. The patient, who is a young man of rather strong constitution, has been labouring for the last fortnight under an extensive eruption, accompanied by sore throat, fever, and severe nocturnal pains. What is principally remarkable in his case is, that he has taken a considerable quantity of mercury, he has been salivated twice, and his gums are still swollen and tender.

It appears from the history of this case, as communicated by the gentleman who sent him to the hospital, that he got a chancre about two months ago, for which he took mercury rather irregularly, and at a time when he was frequently exposed to cold, and following all his ordinary habits. The chancre healed up, and matters seemed to be going on well, but about a fortnight afterwards, having drank rather freely and exposed himself to cold, the chancre broke out again. He again commenced the use of mercury, which he took as before, irregularly, and in a way in which its beneficial action was likely to be deranged. The chancre began to heal a second time, and he was still keeping up tenderness of his gums by the use of diminished doses of mercury, when he was attacked with secondary symptoms.

Here we have chancre re-appearing after free salivation, and a secondary attack coming on at a time when the patient's mouth was still affected. I do not know whether at the present day any person would argue that the symptoms present in this case were not syphilitic, because they had appeared at a time when the man was under the influence of mercury: but I recollect the time when such doctrines were very generally received. Any person, however, who would take the trouble of examining him, would readily see that his symptoms are decidedly syphilitic. It is true also that he labours under the bad effects of mercury; for patients who take mercury for syphilis in an irregular manner, and who follow their usual habits of living at the same time, *are very apt to suffer simultaneously from the unfavourable influence of mercury and the syphilitic virus*. Hence we see how difficult it is to remove syphilis by a badly managed course of mercury. This is the secret of the manner in which many inexperienced practitioners destroy the health of their patients; they contrive that the patient shall suffer from all the bad effects of mercury and syphilis combined. There is nothing peculiar in syphilis with respect to this untoward complication. Suppose a man labouring under arthritis applies to me for advice; or suppose a patient with acute sciatica requests me to undertake his treatment. Here there can be nothing better adapted to check inflammation than the rapid administration of mercury. The same thing is true of many other diseases in which mercury affords the most speedy and effectual mode of relief. But if, instead of telling a patient labouring under iritis, or arthritic inflammation, that he must confine himself to bed, and use a low diet with diluents, while taking mercury, I permit him to drive out in an open carriage, to expose himself to cold, to work, to be intemperate, and to use a heating diet, what is the consequence? His arthritis gets much worse, other joints are attacked, his fever is increased, and with it his debility, yet all this time he is under the full influence of mercury. Or, if it be a case of iritis: the pain, lachrymation, and dimness of vision increase; large quantities of lymph are effused on the surface of the iris, the pupil is closed up, the inflammation extends to the deeper tissues of the eye, and sight is irrecoverably lost. Yet this may occur at a time when the gums are excessively swollen, and the patient spitting profusely. I wish to put this point in the strongest possible way. I will engage, in a case of any disease curable by mercury, to affect the constitution without benefiting the complaint in the slightest degree; to make the patient far worse than he was before; to place him in such a condition that he will labour under the original disease in an aggravated form, and, in addition to this, under the unfavourable effects of mercury. So true it is, that by want of proper care we not only abuse the best instrument we possess, but also generate a new state of things which totally precludes its employment. This is the true explanation of the reappearance of primary or secondary symptoms in many cases of syphilis. The case before us furnishes a most valuable illustration. He got chancre and took mercury irregularly; the chancre disappeared, but on some slight excess in drinking and exposure to cold it returned. He then took more mercury (still irregularly); the chancre began to heal; he continued the mercury in diminished doses, but so as to keep up the soreness of the gums, and, while his mouth was still affected, secondary symptoms appeared. I will venture to say that one-half, nay, one-third of the quantity of mercury he has used would have been quite sufficient to eradicate the disease, had he been confined to bed, or a warm room, lived low, and reduced any febrile symptoms present by proper antiphlogistic means.

COURSE OF LECTURES ON THE THEORY AND PRACTICE OF MEDICINE.

Delivered by C. J. B. WILLIAMS, M.D., F.R.S., Professor of the Practice of Medicine, and of Clinical Medicine, at University College.

Remittent fever is supposed to be an aggravated state of the intermittent, and arises from the influence of the same cause, malaria, acting on a great weakness of the constitution of the subject, so that in a very weak person the same poison that would in others produce intermittent fever, may in them cause remittent fever. Malaria in warm climates is developed in the highest degree, and the greatest strength, on marshes and the banks of rivers. In cold climates intermittent fever prevails, and in very warm climates the remittent. With regard to the effect of this, I have said that the paroxysm is nothing more than the reaction of the vital powers against the cause operating, and we find in remittent fever that cause will be more permanent, or in a greater degree, and keep up a more continued action. We have the parallel of this in the various disorders hitherto considered. For instance, take the case of epilepsy: in many instances we observe structural disease of the brain and nervous centres, accompanied by coma, but which does not exist in its most severe form, then structural disease may be present to a considerable extent, and when the diseased action has gone on so long as to produce disturbance it causes a fit. Asthma arises from the same cause, increasing more and more up to a certain extent. In the one case the same cause increases and accumulates till it produces a fit; and in the other, being in continual operation, it produces remittent fever. The same thing may be said of gout, gravel, and so forth, and in all other fevers, particularly those of slighter disorders, before the paroxysms come on, and during this period the disorder may be produced in the system, but it is insufficient to amount to a febrile stage. The depression does not reach its greatest extent, and the reaction is not developed; very often in connexion with this there are diarrhœa and irregularities in the secretions, and then the remittent fever becomes pronounced, cold chills followed by heat, frequent pulse, headache, thirst, nausea, pain in the limbs, hurried breathing, and general febrile reaction. This fever may exhibit various complexities: sometimes delirium; pulse hard and quick in the hot stage; heat of surface; urine scanty and high coloured; tongue furred; the epigastrium tender; the bowels costive; and this may continue from eight to sixteen hours, when some abatement of the symptoms may occur. This may be more or less complete, and last from a period of from two to six hours generally in persons of temperate habits, and in temperate climates.

In hot climates there is no cessation of the fever, by which it is distinguished from the intermittent. In this type of continued fever reaction predominates, and eclipses for a time the depression. There is a marked cold stage, though it is short; there is, however, shivering, a symptom which announces strong reaction; the pulse becomes firm and frequent, the skin very hot and dry, &c. There is a resemblance between these idiopathic fevers and inflammatory symptomatic fever, but there is this difference: the excitement is more general, affecting the whole system; there is more cerebral excitement in symptomatic inflammatory fever, and it likewise takes place independently of the inflammation, though there may be local disease. This variety is most apt to occur in persons of a sanguine temperament, who are naturally strong and excitable. This kind of fever is comparatively rare; the other variety, a class of the typhus or typhoid form of fever, presents chiefly the group of symptoms peculiarly characteristic of endemic fevers—symptoms indicating depression of the functions generally, vitiation of the secretions, &c.

There is the adynamic variety of typhus fever, characterised by great debility, soft compressible pulse, the circulation generally weak; the surface not hot, or only partially so, and sometimes cool; tongue dry; deficiency of the secretions, and soreness; this variety occurs especially in weak subjects. The second variety of typhus fever is of the nervous or cachectic kind, or low nervous fever, the disorder affecting more particularly the nervous system, and in different ways; often by a slight degree of excitement; the patient sleeps not at all, or very imperfectly; great restlessness, tremor, or spasms, and apparent deafness; the pupil is contracted, although it is in some instances dilated; there are various hallucinations of the senses and delirium, generally of a low kind, ultimately passing into stupor. These are the symptoms of typhus fever, with predominance of nervous disorder and derangement of the sensorial functions. This variety is apt to occur in cases where the nervous system has been previously excited, as by great mental exertion. Persons who study hard, or over exert their minds, falling into fevers, or suffering from typhus fever, are apt to present this variety. Persons in the habit of indulging freely in intoxicating liquors or opium are also apt to suffer from this variety.

The third variety of typhus fever is the congestive form. The effect of this is to oppress the functions; the congestions which are produced, apparently by the primary operation of the cause of the fever, are such that the subsequent reaction is insufficient to remove them. In this congestive form of fever, it would appear the congestions prevail throughout, and to such an extent as not only to disorder the circulation generally, but to oppress individual functions. In these cases you find the pulse feeble, irregular, and soft; great weakness and various functional disorders; coma or stupor in a great degree, sometimes accompanied by spasm, subsultus, delirium, and symptoms of partial irritation; vomiting, diarrhœa, from congestions of the abdominal viscera; and dyspnœa from congestion of the lungs. In some cases this is a sign of great malignancy of the fever. It is a sign of the cause producing, to a greater degree than it usually does, effects commonly observed to arise from the complications of these causes; and accordingly we find that this congestive form of fever sometimes occurs in the worst epidemics, and sometimes actually is fatal in the first forty-eight hours, as if the system was overcome by the influence of the exciting cause. In some cases there is scarcely any febrile reaction, and even in other cases the febrile reaction is but slight; there is muttering delirium, singular heat of skin, and so forth, and a brown dry state of the tongue at the commencement of the disease; the breathing usually is much oppressed and disturbed, and the pupils dilated. In this form, too, there is a disposition to run into gangrene, and it very often happens that there is not only congestion of blood in the entire body, but a great alteration of that fluid. It is more fluid and darker than usual, and deficient of fibrin; and it is this state, where it exists to its greatest degree, that constitutes the putrid kind of fever. There is a disposition for the parts after death rapidly to run into putrefaction, and the secretions are uncommonly fœtid. There is a destruction of the vital powers.

These are the chief varieties of fever, and they may be differently affected by various circumstances, and may pass one into another. Varieties occur in the complications of fever, and the most dangerous are those of the typhoid kind, complicated with local affections. Inflammation, or congestion bordering on inflammation, accompanying fevers may arise in the course of the disorder differently from other inflammations. In some respects they differ in the symptoms which accompany them: these are usually much less permanent, the pain is less acute, the sensibility being in fact generally limited by the cause of the fever or the accompanying congestion. The symptomatic excitement is also diminished. You find, too, that the fever modifies inflammations occurring during its course, and may modify other inflammations in a remarkable degree. If there is inflammation of the surface of the skin, during the fever it will become more congestive, and discharges have occurred from ulcers previously existing, which were dried up or changed in their character. The inflammations of complicated fevers may arise with the fever, sometimes as the result of the same cause simultaneously applied. In other cases they arise out of the febrile action. You remember the congestions fever produces, and you see there are other modes in which fever leads to the production of inflammation. In the alimentary canal, for instance, causing inflammatory matter to be secreted there.

Now we have to speak of the complications affecting the head. The pain sometimes accompanying fever is very severe, and there is occasionally more or less of symptoms of phrenitis, or meningitis, intolerance of light and sound; sometimes nausea and vomiting, indicative of cerebral inflammation; delirium; beating of the arteries of the neck and temples; flushed face, and disturbance of the sensorial functions. The delirium may be more or less complete or partial; subsultus, spasm, and coma, may be present with these complications, less permanent than in simple meningitis. This variety is most apt to occur in hot seasons, and in hot climates; and the chest complications, on the other hand, are more commonly presented in cold seasons and cold climates. The symptoms are cough, dyspnœa, sometimes croupy breathing if the trachea is chiefly affected, slight pain in the chest, tenderness, and soreness. But the symptoms complained of are much fewer than those that may be discovered by auscultation. In the posterior parts of the lungs the complications that occur in the course of the fever have their origin commonly in congestion, this congestion being of the hydrostatic kind, or increasing most in dependent parts. The most general complications are bronchitis, pneumonia, &c. These are apt to occur if there be cerebral complication at the same time. This complication, too, sometimes occurs with the commencement of fever, as the common effect of the exciting cause—a cold. Sometimes it arises in the course of the fever in the early stage, and sometimes from cerebral complications. Besides these complications, tubercles are apt to occur in the course of long-continued fever, affecting chiefly the posterior part of the lungs, which are the chief seat of the congestions.

The abdominal congestions are very numerous, and hepatic congestion and even inflammation is common in hot climates, accompanied by symptoms of more or less uneasiness, tenderness, and fulness in the right hypochondrium, occasionally jaundice; and these symptoms are not at all unfrequent in the fevers of this country, particularly in the early stage, connected with congestion. The liver bears a most important relation to the venous system; and in intermittent fevers it partakes of these congestions to a great degree. Intestinal disease is by far the most common complication of the worst form of continued fever; it is often extremely insidious, causing a gradual increase of the febrile symptoms and an increase of the sensorial disturbance. When this complication comes on, the tongue becomes brown and dry, and redder at the edges; the skin is hot and dry, the bowels relaxed, and the evacuations disordered, being dark and fœtid; after a time they become watery; there is not unfrequently tympanitic distension of the abdomen, and a large quantity of gas is excreted. The inflammation in these cases is chiefly follicular, leading to ulceration. The abdominal complication is a serious one; it increases the danger considerably, and the difficulty of treating the fever. This danger is not confined to the low stages of the fever: even where the patient recovers from the fever, the diarrhœa continues; the tenderness of the abdomen and the discharge from the intestines prove that ulcerations occur; traces of blood, and sometimes pus, are seen in the evacuations, and the diarrhœa occasionally proves fatal after recovery from the febrile stage of the disease has taken place. In some cases, the ulcerations lead to perforation of the intestines and other parts. Affections of the urinary organs are less common in fever than affections of the other parts, but retention of urine is not at all an uncommon occurrence. It is of great consequence to see the way in which the water is evacuated. Sometimes it passes involuntarily; and, under these circumstances, it frequently happens that the bladder is very much distended. It it very important, in these cases, to guard against gangrene.

The morbid anatomy of fevers does not present so much as we should be led to expect from the fatality of the disease. In some cases of the adynamic kind there are no morbid appearances to be found, or none that can be considered as decidedly morbid. Congestion of the viscera is of the most common occurrence, and a fluid state of the blood. There are no visceral changes, no changes of structure, though there may be local affections, which are far from being in proportion to the severity of the symptoms. In nervous cases the congestion will be found principally in the head, but there is more or less of congestion in all parts of the interior of the body. In some instances it has gone beyond congestion, and blood has been extravasated into the textures, which are tinged of a claret colour. Sometimes considerable effusions of blood are met with in the congestive kinds of fever. I have seen cases in which there were petechiæ on the surface of the body and external organs, with patches of blood or spots throughout their substance; and considerable collections of blood in different parts, such as the abdominal vessels, the lungs, &c. If the disease has lasted many days, besides the congestion, there is a good deal of softening of the tissues, in which the blood has accumulated; and there is a great tendency to run into decomposition; all the textures exhibit a softer condition than they do long after death from other causes. The abdominal complications of fever are the most frequent, especially in the follicular membranes and the glands. These complications are supposed by the French pathologists to occur constantly in typhus fever; and they appear to be so constant in Paris that it is difficult to separate the two. The same appearances are observed in the fevers in this country; but it is remarkable that at Glasgow, Edinburgh, and Dublin, it is often absent. The complications are most marked in young subjects, where the fever is of long duration; and seeing, therefore, that in all subjects it is not in proportion to the severity of the fever, but rather its duration, we can scarcely draw the conclusion that it is an essential part of the fever.

With regard to the symptoms of the two kinds of fever, they are continuous, and not to be distinguished from each other. We have assumed, and we are thoroughly warranted in assuming, that typhus fever is the result of the operation of the poison; and the other effects of this poison we have traced in the disorder of the functions; occasionally we find local effects arising from it, and we find the same thing occasionally arising from other poisons. In the thoracic complications there may be signs of bronchitis, of pneumonia, and more rarely those of pleurisy: the lower parts of the lung are engorged, of a dark red colour, soft and fragile under the fingers. Parts of the lungs are often partially consolidated; slight eruptions occur in some of the congestive forms. This differs from common inflammation. Sometimes there is a trace of lymph, and sometimes pus, just enough to show the occurrence of an alteration of structure. The blood is greatly altered, and does not coagulate; it rarely presents any buffy coat, and when it does it is very loose indeed; it is deficient in fibrine, and from the experiments of Andral and Cruveilhier, it would seem that the colouring matter becomes changed in some way.

The diagnosis of fever is to be founded on the consideration of the chilly heats and febrile pains that occur in the early stage of the disease, without complication with any local visceral affections. Mark the occurrence of head-ache, giddiness, stupor, or heaviness, or disorder of the senses, or delirium, extreme weakness, and tremors; the tongue exhibits a tendency to dryness and soreness, and there is a peculiar dryness of skin; the pulse is frequent, and in most cases weak, in comparison with the amount of febrile disturbance. Fever is to be distinguished from inflammation of the brain by the weakness and the state of the tongue, which is furred, brown, or dry; and from delirium tremens, by the great debility, the great amount of prostration, and there not being that quickness of the senses so remarkable in delirium tremens; there is a sort of stupor and heaviness, and an absence of that peculiar fœtid sweat that occurs in delirium tremens. From suppurative phlebitis it is to be distinguished by the preceding symptoms; fro

enteritis by a less degree of pain in the abdomen, and a greater degree of stupor.

The prognosis of fever is a matter of considerable importance. It is always a serious disease when it continues; even cases slight at first may become very severe in their course. The rate of mortality is as one in ten. This is a low rate. In bad epidemics the mortality is one in four, or one in two. Generally speaking, it is less fatal in females and young subjects than in men or those of ad vanced age. The simple forms of fever are dangerous in proportion to the prostration, especially where the symptoms of weakness come on very early, and are accompanied by symptoms of congestion. The complicated forms of fever are the most fatal. The pulmonary and intestinal complications are very dangerous, especially when they are of long duration. The disease is more fatal in children than intermittent fever. It is more common in the adult age, and in persons of feeble and intemperate habits.

MEMOIR IN REPLY TO THE FOLLOWING QUESTION, "CAN A DISEASE IN ITS VARIOUS STAGES BE CONSIDERED AS CONSTANTLY IDENTICAL?"

By P. A. PIORRY, M.D., M.A.M., Professor of the Practice of Physic at the University of Paris, Physician to La Pitié, &c.

For the Medical Times.

On taking a rapid review of the mode in which medicine has been studied from the most remote times up to the present day, the observer is obliged to admit that hitherto arbitrary collections of symptoms, to which a peculiar and isolated existence has been attributed, have alone been taken into consideration. In fact, it was remarked that owing to a cause certain phenomena appeared, which were supposed to succeed each other in a regular manner, and to these phenomena the term *disease* has been given.

It could hardly be otherwise; we form abstract ideas from analogies deduced from material objects which fall under our notice, and the abstraction *disease* is therefore naturally considered as a reality. Heat, or the *pyritos* of Hippocrates, febris, pestis, erysipelas, icterus, and, at a later period, catarrhus and rheumatismus were supposed to be such; so that, after ascertaining their existence, it was thought possible to reckon them, and the description of the reunion of certain symptomatic phenomena hitherto unnoticed was considered to be a real discovery.

All the doctrines, all the discussions turned on this pivot. Hippocrates admitted a certain number of diseases; and after the father of medicine, Galen, Themison, Cælius, Avicenna, Fernel, Stahl, Sydenham, Boerhaave, the iatro-chemists as well as the vitalists, did the same. All coincide in the opinion that diseases are unities, therefore nosologists classed them as botanists do plants, and statisticians counted them in the idea that they could thus reduce the mobile face of nature to the certainty and invariability of cyphers.

Diseases having been thus particularised, isolated, counted, the next thing sought for was the indication of the most appropriate methods of treatment for each, and these, in their turn, were particularized, isolated, and counted. The most learned treatise on therapeutics, the most ignorant productions of charlatanism, agree, inasmuch as the chief aim is to establish treatments, formulas, and receipts against any given disease designated by such or such a name. The most distinguished physicians, the most illiterate nurses, do not consider under any other light the various means employed to relieve human sufferings. At the present day practitioners seek to discover a plan of treatment for *typhoid fever, rheumatism, cholera*, &c.; the progress of science has scarcely glanced at the mode of reasoning, evidently contrary to observation and rational therapeutics.

The true practitioners of all ages have never ceased to say, "Pathological descriptions are very seldom met with by the bedside of the patient." That given by Hippocrates of a disease is applicable to affections of a very different character, for which the most opposite mode of treatment is requisite. Typhoid fever comprises the great majority of all acute febrile diseases, and in cases thus denominated there are at least ten in which the treatment must differ. The same remarks are applicable to rheumatism, icterus, and cholera. The works which have been published on clinical medicine give but a very imperfect idea of diseases; what is requisite is to indicate the means by which they may be easily recognised. The description of such or such a disorder is given, but it is impossible to find by the bedside of the patient the symptoms invented by the lucubrations of a fantastical mind, since they vary every moment in the same individual. Inflammatory previous to venesection, they become bilious the day after, mucous at a somewhat later period, then adynamic, and finally ataxic, if nervous symptoms appear. This is not the foundation on which clinical medicine can be established, nor is it the means by which the practitioner can be enlightened. The theory ought to be made to agree with clinical observation; positive signs ought to be given by which the observer may be guided in this therapeutic labyrinth; characters ought to be indicated, by which it may be said with certitude, in such a case, these remedies are requisite; on the contrary, in another, very different ones must be had recourse to. The descriptions ought to be presented in such a way that the idea formed of any given disease indicates necessarily the mode of treatment. Unless this is done, how is it possible for practitioners to profit by the works published or the doctrines they contain?"

It is thus that men who study diseases as they ought to be studied reason; their reproaches are terrible arguments against the mode actually adopted in the practice of medicine, and against the admission of the abstraction *disease*. If the clinical observer cannot be guided by the doctrine which admits this abstraction, evidently this doctrine is erroneous, inasmuch as the practitioner studies nature, whilst most authors on pathology have written their treatises in their studies.

It is supposed, in admitting the being *disease*, that a cause or a series of causes act and produce a morbid condition, and then a reunion of phenomena which are constantly the same, among which is included what is denominated reaction, followed by accidents united in a more or less precise order—accidents terminated by health, infirmities, or death. This disease differs from another affection, in which other morbid causes give rise to a series of phenomena followed by a very different result; whence the necessity of as many varieties of diseases as there are varieties of causes and peculiar symptoms; whence, again, the description of each of these diseases is totally different, and quite distinct from that of any other affection.

Nothing is more erroneous than the opinion here alluded to. No cause can produce the same result unless it exercises its influence under circumstances precisely similar, otherwise there would be as numerous varieties in the result as the circumstances which cause it differ. Now a morbid cause presents various degrees of intensity, and is influenced by coincidences of a very different nature, besides which they act primitively or consecutively on numerous organs differently disposed, and influencing each other variously in each individual, so that the effect produced by a cause, unique in its nature, is on one person dissimilar to that produced on another.

What will it be, then, when several causes, as is usually the case, unite to produce morbid phenomena? Will there not be a complication of causes, complications in the primitive results, complications in the consecutive symptoms, and augmentation in the intensity of these complications by secondary causes which induce a more or less advanced stage of the disease? How is it possible in such confusion to discover diseases simple in their nature, which are always identical, and which develope themselves constantly in the same way?

Thus it is impossible in theory, and clinical facts come to the support of this opinion. Let us take an example among a thousand:—Variola, a model of a disease, in which a specific and unique cause exists. Now, is there in the eyes of the medical man the least resemblance in the symptoms, prognosis, and especially the treatment, of varicella, discrete and confluent variola, variola complicated with laryngitis or bronchitis? There are not perhaps, two cases out of ten, the organic condition of which is analogous, and which require precisely the same remedies. Again if we take diseases the causes of which are still more complex, for instance, *typhoid fever*, the difference would be still greater.

The limitation of a morbid state under the denomination of the term *disease* is perfectly arbitrary. One author gives to inflammatory fever, pneumonia, pleuritis, or apoplexy, limits which another refuses to admit, or which he increases or diminishes at will. One pathologist recognises with Cullen, Pinel, &c., some hundred diseases, whilst another with Sauvages, counts them by thousands; all depends on the number of symptoms arbitrarily grouped together. Reasoning thus, why should not a million diseases be admitted with as much right as a few?

One of the greatest therapeutic errors which has ever been committed, is to imagine for a moment that it is possible to determine by statistical tables founded on a base formed by complicated disorders, what is the best mode of treatment that can be employed. In a very important discussion which took place some time ago, at the Royal Academy of Medicine, on the pretended statistical doctrine, the principal argument advanced by me, and developed afterwards by several members of that distinguished body, was the following:—Disease is a compound of the lesion of a great many organs; each of these lesions presents in each disease different degrees, so that it is impossible to form through their means similar tables. Suppose we represent by the letters of the alphabet the various pathological conditions presented in a disease; for instance, we call plethora, A; pulmonary congestion, B; lesions of the intestines, C; those of the skin, D; those of the liver, E; those of the spleen, F; &c., it is in vain that the practitioner would endeavour to unite in two patients an equal number of letters, so as to form some word. Nay more, as each of these conditions represented by a letter varies in degree, in character, and sometimes in its peculiar nature, it is not only impossible to obtain an identical, but likewise an approximative, result.

But in support of the opinion advanced, that the disease ought to be considered as a unity, it has been said, there are peculiar causes, peculiar symptoms, peculiar modes of development and of termination. This constitutes the disease, the rest is but accessory, and forms the complications, the accidents. Those who do not admit the unity of a disease are accused of being themselves in the details, of not possessing the *coup d'œil* of the whole, of being like the painter quoted by the poet, who was capable of delineating in a perfect manner each part of a picture, but who had not sufficient talent to understand the whole, and to place its various parts in such a way as to make them harmonise with each other.

In order to give some weight to these objections, it is necessary that the *principal symptoms*, the *predominant lesion* should remain always the most important during the duration of what has been denominated disease. Now this is not the case; for instance, in the numbers of complicated symptoms designated by the term *typhoid fever*, we remark, in the first stage, that the condition of the blood and enteritis are the *chief symptoms, the real affection*; at a later period, it is either pulmonary congestion, or intestinal tympanitis or an affection of the spleen, finally there is almost always towards its termination, anæmia; *all these various lesions constitute the most important phenomena of the disease.* Again, in variola, the alteration in the qualities of the blood, and the cutaneous eruption, are the principal symptoms observed, and which are according to some authors, all the disease; now if laryngitis supervenes at the commencement, or during the course of the affection, it constitutes the most serious, if not the principal, lesion, and it is this complication, rather than the cutaneous affection, which endangers the life of the patient.

But we may go still further, and state that the reunion of symptoms denominated disease differs so widely in its various periods or degrees, that the phenomena, the diagnosis, the prognosis, and the treatment, are very different in each. For instance, the pulmonary congestion in the first stage of pneumonia is in no respect like the red induration of the second stage, nor is this similar to the yellow or suppurative induration of the third. They form,

and this no one can deny, three very different morbid conditions, the two latter being, it is true, the consequences of the first, but in a pathological, and especially in a therapeutic point of view, they bear no resemblance whatever to each other.

Again, take two cases of pneumonia at the same stage, and as uncomplicated as possible; they will not present the same characters. Thus, in one it may invade a considerable portion of a lung, whilst in the other it may affect only a lobe, or a few lobules. Evidently in these two cases the treatment to be had recourse to cannot be precisely the same.

In order to preface statistical tables, a considerable number of cases of uncomplicated pneumonia were collected; but on reading them over, it became necessary to divide them into several categories, as the symptoms they offered were so different that it would have been an absurdity to combine them with the intent of forming a whole. Taken, therefore, separately, they were read over again, but they were still so unlike that subdivisions were requisite. Finally, each individual fact composing the subdivisions was so dissimilar from the others contained in the same series, that it became necessary to study them one by one. This led naturally to the conclusion that it is impossible to establish positive statistical documents with respect to complex diseases, and that it is necessary to found the basis of numerical researches as much as possible on uncomplicated diseases.

It must, however, be supposed that the authors who form these theories on diseases considered as unities, adopt in the treatment of their patients those obsolete hypotheses to which they endeavour to give a more youthful appearance by bestowing on them *another shape*. In no wise; those who seem to take such delight in their statistical hallucinations scarcely attend to the name of the disease when at the bedside of their patient. Let him be affected with a typhoid fever of a bilious, mucous, or adynamic form, if on examining the lungs they discover that pneumonia exists, they are of necessity obliged to neglect the former, and employ remedies appropriate to the relief of the pulmonary phlegmasia. They perceive themselves that their doctrines are erroneous and incomplete, since they, in describing the history of a disease, enumerate its complications, and give thus a general treatise on almost all the diseases to which humanity is subject.

Thus, in a theoretical and practical point of view, disease, considered as a reality, is a pure abstraction; but it must not be viewed in that light by the bedside of the patient. In a second Memoir, that which constitutes the foundation of sound theory and practice will be examined.

PENCILLINGS OF EMINENT MEDICAL MEN.

PHILIP PINEL.

(Continued from page 229.)

Occupied by such various subjects, he wrote for the *Encyclopedie Methodique;* he had undertaken to translate *Cullen* and an edition of *Baglivi;* he studied botany under the directions of his friend Desfontaines, and chemistry under the judicious J. d'Arat and the eloquent Fourcroy; Pinel, contented with his present position, and quite secure, or perhaps careless for the future, had no wish to practise, for though he attended the clinical lectures at the hospital, he refused all occasions of seeing and treating patients. He was, however, in 1783, grieved by the loss of a young man to whom he was much attached, and who, from hard study and excessive continence, lost his reason. This unfortunate young man, on his return to the bosom of his family, went raving mad, and fled one evening from his father's house into a neighbouring wood, where he was destroyed by wolves. The next day his torn remains were found, and near them a copy of Phedon covered with blood. This catastrophe had a great effect on Pinel's mind, and was perhaps the cause which first directed his attention to the study of this powerful malady, which was then so imperfectly known. About this period an establishment was formed for insane persons, and the first patient received in it was placed there by Pinel. It was then that in all probability he made the first trial of the innovations which will cause him to be blessed in all future ages. For the compulsion and restraint employed everywhere else against the fury which characterises mania, and which is so deserving of commiseration, Pinel substituted treatment, in which justice was softened by kindness. He allowed quiet patients to go about at perfect liberty, and employed restraint only on those whose violence rendered them dangerous; but even with these he made use of it in such a manner, and within such limits, that the patient's sense of right, far from resisting, yielded very readily; for it is extraordinary that, on the contrary, even in the greatest disturbance of the mind, the sense of right never disappears. It is this feeling which the physician ought always to husband in the heart of the patients, and which, sooner or later, will open the fortress to him.

The success which during six years attended this method, sanctioned its use; when, in 1792, the Royal Society of Medicine of Paris proposed the following as a prize question—*Indiquer les moyens les plus efficaces de traiter les maladies dont l'esprit est devenu aliéné avant l'age de la vieilesse* (to point out the best mode of treating patients who have become insane before old age)—Pinel competed. His work mentioned at the public *séance* held on the 28th of August, 1792, bore the following motto, taken from Celsus—*Genere sc pro cujusque natura necessarium.* A motto fraught with meaning, and applicable to all kinds of diseases; but, above all, to insanity. But did Pinel obtain the prize? His manuscript, left incomplete or mutilated, tells us nothing on that head; but the *Memoires de la Societé Royale de Médecine* would, in all probability, have informed us, had they not been interrupted by the troubles in the political world. Be this as it may, Pinel soon after received a prize more worthy his acceptance—a prize which became the source of glory to science, and usefulness to mankind. Thouret was a member of the Royal Society, and formed part of the committee appointed to examine the memoir presented by Pinel, the perusal of which made him esteem the talents and character of its author. The changes which occurred in public affairs placed Cousin, Thouret, and Cabanis at the head of the administration of the hospitals, which, in spite of the reforms attempted by the most humane of our kings, were, in the capital, in a state of the most deplorable inhumanity; and Bicêtre was the one which presented the most scandalous aspect. Vice, crime, misfortunes, and infirmities, persons afflicted with the most loathsome diseases, and with diseases of a very different nature, were huddled *pele mele* into the wards; no distinctions were made. The buildings were uninhabitable. Men covered with filth remained motionless in narrow, cold, and wet stone cells, deprived of air and of the light of day, and only furnished with straw to lie on, which, as it was but seldom changed, soon became rotten and full of vermin; horrible dens, into which we should hesitate to put the lowest animal. Insane persons, shut up in those *cloacæ* were at the discretion of their keepers, who were criminals taken from prison to perform these duties. The unfortunate patients, loaded with chains, and bound like galley slaves, were abandoned to the cruelty of these men, who made them objects of the most insulting raillery, and of a brutality the more disgraceful, since it was perfectly gratuitous. This injustice and cruel treatment, filling them with indignation, despair, and rage, caused their wandering reason to stray still more, and drew from them, day and night, howls and screams, rendered still more frightful by the noise of their chains. Some more enduring or greater dissemblers than the rest, appeared insensible to the violence exercised towards them; but they concealed their resentment in order to make more certain of revenge. They narrowly watched the movements of their tormentors, and, when able to surprise them in a convenient attitude, they struck them with violence on the head or epigastrium, and laid them dying at their feet. Thus there was on the one side cruelty, and on the other murder. Once engaged in this criminal direction, how could it ever be put a stop to? and what amelioration in mental affections could be expected from such dreadful retaliations?

The three administrators lamented this mixture of crimes and misfortunes; all three were Pinel's friends, and all three felt convinced that Pinel was the only man in Paris, and perhaps in France, who was capable of remedying such accumulated evils. He was accordingly named Physician to the Bicêtre, and began his duties towards the close of the year 1792.[1] With him, compassion, attention, regard, kindness, and justice entered the asylum—virtues, whose soothing influence in cases of even the most furious mania, he had had ample opportunities of observing. Things soon presented a very different aspect; but in order to avoid the danger attendant on any great change, it was made gradually. A man was then at Bicêtre, whose instinct had to a certain degree made him the forerunner of Pinel, a man who, though he had received but little education, was endowed, notwithstanding his natural severity, with good sense, great tact, and a kind and feeling heart; Pussin, who, disregarding the fears of some, of the clamours of others, had already dared to remove the fetters from some of the unfortunate sufferers.

This trial having been successful, the remainder was accomplished under the enlightened direction of Pinel, the patients being no longer disfigured by the exasperation, or terror, produced by bad treatment, their diseases assumed their natural physiognomy, and allowed the judicious practitioner to study them in a regular manner, and to give a true and accurate description of them. For two years Pinel was the benefactor of the Bicêtre, and at their expiration he was requested to undertake in a second hospital the humane and advantageous revolution he had accomplished in the first; I mean in the Salpetrière, where the same excesses reigned. The insane women who had previously been treated in the Hôtel Dieu, were received in this asylum. This treatment was incomplete, and common to every species of insanity; thus increasing the danger of the disease, and rendering it more difficult of cure. To keep their passions within due bounds, the unfortunate creatures were submitted to the severities already mentioned, or it may be rather said, were irritated by the same oppressive measures. Enchained sometimes naked in almost subterraneous cells, worse than dungeons, their feet were often gnawed by rats, or frozen by the cold in winter. Covered by wounds, their embittered hearts breathed nothing but vengeance; and, carried away by the hatred which absorbed them, they sought, like bachantes, only to injure the women who watched over them, or to hurt one another. Who could suppose it?—obstacles without number were raised against the plans proposed by Pinel, though experience spoke in his favour, and though the method (which he endeavoured to abolish) founded its necessity on the evils it caused. But it is thus, says Montesquieu, that cruelty ever reasons. At length, however, the administration perceived that the treatment of mental alienation needed, more than any other class of diseases, a perfect unity of design, as well as a great variety of remedies. The patients were consequently removed from the Hôtel-Dieu, and placed entirely in Pinel's hands, who, assisted by the person of his choice, the faithful Pussin, set aside habitual opposition and interested errors as vain shadows, and was enabled to substitute order for chaos, rules for caprices, and the sacred rights of humanity for the shameful excesses of cruelty. These reforms have remained to the present time, having been continued by Esquirol, and followed by the administration, which has extended them to the most minute details. From this it is that the Salpetrière may now rank among the best asylums consecrated to misfortune.

But science especially has profited by it. Diseases being classed methodically at the Salpetrière, as at Bicêtre, were observed with greater care, and consequently were better known and more accurately described. After several essays communicated to various learned societies, and inserted in the collection of the Memoirs of the *Société Medicale d'Emulation*, Pinel published, in 1801, the result of his laborious researches, and this work, revised and corrected by the author, appeared in 1802, under the following title; *Traité Medico Philosophique de Alienation Mentale.* This work, preceded by another of a more distinguished style, to which allusion will

[1] See num. de l' Acad. Royale de Med. Paris, 1836, vol. v., p. 31.

presently be made, established Pinel's celebrity; in fact, this treatise on mental alienation is an evident proof of the originality of the author's mind. In it Pinel examines, far more profoundly than his predecessors, the peculiar nature of acute mania; he teaches us to consider it as an act of the living powers which must change our organisation—an act which science may retard, disturb, or pervert, by a rash mode of treatment, but of which the acuteness alone ought to be moderated, in order that the disease may go through its natural course and terminate without being interrupted. Unseasonable remedies or spontaneous obstacles precipitate it too often towards those unfortunate terminations, which, after disturbing its primitive direction, sometimes allow it to reappear under the same form, or at others pervert and perpetuate it under a new and henceforth immutable shape. With respect to the different forms insanity may put on, Pinel classes them under the four following heads: mania, melancholia, dementia, and idiocy. This division is spacious; it comprises, without doubt, the most important diseases, but still it is not sufficient; for however considerable the perspicuity it brought to the study of so protean a disease, it is now known that such a classification cannot embrace all the lesions, when uncomplicated, and still less so when combined with other affections, which happens unfortunately too frequently in the moral and intellectual part of our economy. I mean in our sentiments, our ideas, our will, and, what cannot be separated therefrom, our movements and our actions; for these are the parts which are governed by the operations of the mind, and which in insanity escape or resist its power. Nay more: Pinel did not carry his analysis far enough, since he comprised under the same head mania without delirium, which is an uncomplicated disease, and mania with delirium, which is a complicated affection. In fact, there is uncomplicated mania, or, what is the same thing, there are aberrations of the mind, and there are species of melancholia, of despair, of furor, and of anger, spontaneous and instinctive, without reflection, and free from all influence of the mind, which lead man to injure himself, or conduct him blindly to commit murder; there are also others which do not affect the ideas, but which are perceived, judged, and condemned by them, and combated by all the powers of the intellect; whence the phenomenon of two wills, so well described by St. Paul, and so badly explained by philosophers. On the other hand, there are certain disturbances of the mind, marked merely by a want of coherency, either in the ideas, or in the acts; in other words, there are kinds of dementia, there are real deliriums, which, being united to no species of furor, at least existing, constitute for that very reason, a simple disturbance of the intelligence, an uncomplicated delirium; whence it is easy to perceive that these two lesions are perfectly independent of each other; and, when co-existent, the result is not a simple but a complicated case, and that the mania with delirium is a combination of furor and dementia. It is equally so with those disturbances of the passions, those sudden and unnatural antipathies, which in the heart of a woman usurp the place of her wonted kindness; horrible impulses which sometimes are overcome by the will, and at others overthrow it, subjugating the intellect of the mother, and placing in her hands a dagger to be directed against her own offspring. Is it not visible that here the mind alone is depraved, and that the intelligence is overcome rather than perverted? What becomes of the freedom of our mental faculties? and how necessary is it, when framing laws on acts of this kind, to distinguish what ought to be pitied and what punished! But to return, I will add that in describing melancholia, Pinel did not always, as he might have done, trace deep enough the causes of the mistaken judgments which characterise it, and which are often suggested to the mind, either by the erroneous perceptions of the senses, or by the sentiment of an internal disturbance, which has all the false appearances of hallucination—a kind of deceitful, though real perceptions, whose principle, though difficult to discover, is notwithstanding, in some cases, the original cause of all mental lesions.

Finally, and this is but a very slight fault, Pinel engages practitioners to perfect themselves in the treatment of insanity, by the study of the faculties of the mind; he refers them, for this purpose, to the writings of eminent men and modern philosophers who have made so sublime a theme the object of their meditations, thus rendering medicine subservient to metaphysics; whilst, on the contrary, metaphysicians ought to become the disciples of physicians, to be able to penetrate into the secret abysses of the human mind. Had they studied in so fertile and necessary a school, neither Locke, though he was colleague to Sydenham, nor Condillac, nor any of their disciples, would have committed the strange paradoxes, which disparage works in other respects a glory to their country and to their authors. I affirm that the study of the whole mind is exclusively the patrimony of medicine. Hippocrates has comprised all these wonders in two aphorisms, which his successors ought to have accepted as their most precious inheritance. But this inheritance they did not recognise, and to such an extent did they disdain to take advantage of it, that this valuable and important part of the science is still enveloped in darkness. Nothing is demonstrated, nothing is put in its proper place, no one part is examined in its relation to the whole; whence it arises, that, among numerous sciences which have no real prop but in this fundamental and principal knowledge, diseases of the mind are so imperfectly known, and, that there is so little concord and uniformity in the denominations given to them by writers. But, however just these remarks may be, it is not less certain that Pinel's work is of infinite value, from the facts, the method and the ideas it contains, and from the moral lessons which it teaches to mothers, fathers, and tutors, who are specially destined to improve the minds of their pupils; for the mind is itself a source of elevated and social sentiments, and of regular and temperate habits.

PROGRESS OF IRISH MEDICAL SCIENCE.

(FROM OUR OWN CORRESPONDENT.)

Dublin, July 12.

New Views from the Hospital Gazette.—In my last communication, I alluded to some cases by Dr. Corrigan, published in the Hospital Gazette; in the same number are recorded a few cases in ophthalmic surgery selected from the practice of Mr. O'Ferrall at St. Vincent's Hospital, not as the writer says, with a view of presenting by a detail of them any new pathological feature, but by way of illustrating some practical points and peculiarities in the mode of treatment which it appeared important to notice.

In one of the cases, a specimen of opacity of the cornea, the exhibition of alterative doses of the bichloride of mercury was resorted to, and the mode in which this was administered, *invariably after meals*, is offered as a point especially deserving of attention.

Now without meaning for a moment to question the value of the writer's intention in placing this piece of information so prominently before the public, and the profession at large, it is but just to the hospital staff of our city to remind him that this mode of prescribing the B. C. Hyd. is one, the advantage of which has always been appreciated by them; and sufficient proof might also be adduced to shew that, even among the less enlightened members of the profession in the provinces (for whose improvement perhaps the announcement was more immediately made), the propriety of the practice is both acknowledged and acted on, nay, it is matter of doubt whether, even in the remote region of the county of Kerry, the custom is not perfectly familiar to her humblest aspirants in the healing art.

Next, speaking of the application of nit. argenti. to ulcers of the conjunctiva, it is observed that considerable difficulty is experienced in scraping down a piece of the solid nitrate to a proper point, such a practice being objectionable too from the danger of the patients suddenly starting under its application.

So to meet this twofold difficulty, we are told that Mr. O'Ferrall has been in the habit of using a fine-pointed cone of soft paper, the apex of which, being impregnated with a saturated solution of the nitrate, is employed as a substitute.

With respect to the use of the paper cone, it is well known amongst the students of the various hospitals, that a precisely similar practice is pursued elsewhere, and with regard to the difficulty of procuring a fine pointed piece of nit. argenti, it may be observed, that a very easy method of effecting this has been adverted to by Dr. Jacob in his lectures on various occasions. It is simply this: dip the end of the pencil of caustic in a little water, and then rub it briskly with a cloth, repeating the process until a sufficiently fine point is produced.

In the absence of matters of immediate interest, I have selected from my note book the following case of laryngitis treated by Mr. Smiley at the Meath Hospital; though not of recent occurrence, it may not be unacceptable to the readers of your journal, inasmuch as it presents a very well marked instance of the success of the operation of tracheotomy, respecting the choice of which in these cases so many and such varied opinions are entertained. The case which follows it, also one of laryngitis, was very recently under the care of Dr. Stokes at the same hospital, and offers on the other hand a remarkable illustration of the value of medical treatment.

Syphilitic Laryngitis; Tracheotomy, Cure.

P. Kearney, ætat. 45, was admitted into the Meath Hospital under the care of Mr. Smiley, on the 17th of May, 1843, labouring under great difficulty of breathing, which had existed, with more or less severity, for two months before.

He has had venereal disease, and has lately been under treatment in this hospital for syphilitic iritis. On his admission, means were used to subdue the inflammatory affection of the larynx.

He was leeched over that part, and ten-grain doses of calomel given every sixth hour; notwithstanding these means, his breathing became more laboured, he could not lie down all night.

There was total loss of voice, respiration was stridulous, and at each inspiration the epigastrium was drawn in. On the morning of the 19th he seemed to be moribund, his face was livid, he had been delirious during the night, and now lay comatose. There were convulsive twitches of the muscles of the lower jaw and abdomen, the pulse was feeble and indistinct, and sordes had collected about the lips and teeth. It was feared the patient was too far gone to be relieved by an operation; this was, however, undertaken, and performed in the usual way; the trachea being exposed, a portion of one of the rings was cut away, and a silver canula inserted, through which a large quantity of bloody mucus was expelled. Shortly after the operation the patient was much relieved, his natural colour returned, and the stupor disappeared. On the 20th the canula was withdrawn, and the lips of the wound were kept asunder by an elastic bow-shaped piece of iron.

22nd.—Expectoration goes on well through the wound; his mouth is sore; has mercurial dysentery.

27.—General condition much improved; can speak intelligibly. Mercurial fumigations ordered.

June 5th.—Wound has quite healed; breathes freely through the larynx; his voice is restored.

23d.—Was discharged, having remained in hospital under inspection in excellent health since last report.

Laryngitis treated by Dr. STOKES.—Clinical Clerk, Mr. WM. GOODLAND.

John Cashell, a carpenter, æt. 33, admitted May 30, 1845; he was always a strong healthy man, but six years ago he had an affection of the lungs, since when he has been liable to occasional cough; has been a very free liver; about three years before the time of his admission he had chancres, followed by bubo, for which he took a great deal of mercury; no secondary symptoms were observed.

In twelve months after this period, he perceived his voice greatly altered in *singing*—from having been very musical, it became husky, and could only be exercised by an effort—yet, until eight months ago, it had not undergone any very marked alteration; very soon after, however, his speech became hoarse, and inspiration was performed with some difficulty; this state of things increased gradually up to the present time, but has been considerably aggravated during the last few days. His general health was good all through; he had been blistered several times over the larynx, but with little benefit.

He had gonorrhœa and swelled testicle eighteen months ago, but no sores then. On his admission dyspnœa existed to a most distressing amount, and was so great after walking up stairs, as to threaten suffocation; respiration, accompanied by a loud murmur, similar to that of a large humming-top, was heard both in inspiration and expiration, and audible outside the ward; countenance pale and anxious; circulation perfectly quiet; no pain in the larynx, even when pressed on, or moved about; fauces free from ulceration, but a large patch of mucus was seen on the back of the pharynx, which was at first mistaken for an ulcer; epiglottis appeared healthy to the touch; a sufficient examination of the throat could not be made, from the distressing dyspnœa produced by the attempt; stridor[1] is from above; no emaciation; no hectic. The chest sounds well on percussion; respiration natural, but very feeble; cardiac sounds normal.

The symptoms were now so severe, that one of the surgeons present thought that, to preserve life till the system could be got under the influence of mercury, it would be necessary to perform tracheotomy.

May 31st.—Eight leeches were now, however, ordered to be applied to the larynx, and three grains of blue pill with Dover's powder was given three times a day. Ungt. hyd. fort. ℨj. bis horis infriciandum.

June 3d.—The system as yet unaffected by the mercury; the stridor and dyspnœa still very bad, especially at night; spasm of the glottis occurred on two occasions, threatening immediate suffocation, but relief was obtained by leeching; circulation tranquil.

On percussing the larynx, the right side was found to be decidedly duller than the opposite. Eight leeches to the right side of the larynx;—the pills and ointment to be continued.

Under a continuance of this treatment, all the symptoms gradually disappeared, the dyspnœa and stridor undergoing most marked relief when the action of the mercury was established. Hoarseness continued a considerable time, but was relieved by blistering; it existed to a slight amount when he left the hospital, on the 5th of July, declaring that his health, in every respect, never was better.

[1] In his work on the chest, Dr. Stokes alludes to the important diagnostic aid in some of the diseases of the air passages derivable from an accurate knowledge of the situation of the stridor; that from above being indicative of disease in the upper portion of the windpipe, while from the presence of aneurismal or other tumours, the sound proceeds from its inferior extremity.

PROGRESS OF FRENCH SCIENCE.

(FROM OUR OWN CORRESPONDENT.)

Paris, July 3, 1845.

On Local Applications in Diseases of the Skin; by A. Cazenave, M.D., Physician to the Hospital St. Louis, &c. In slight forms of acne, in lichen, pityriasis, herpes, and even eczema, slightly acidulated lotions are very useful. After the scabs have fallen off in impetigo, the following lotions, ℞. Aluminis ℨij.—ℨiij. Infus. Ros. gallic. ℔j. M. ft. lotio. R. Hydrarg. bichlor. gr. ij., Ammon. chlorid. gr. ij., Lact. amygdal. ℔ss. M. ft. lotio may be used with much advantage. When the disease is chronic, Acid nitrici. Acid. hydrochlor. āā m. xxv., Aq. distillat. ℥x. M. ft. lotio. ℞. Alumin. ℨiij. Ammon. muriat. ℨj., Sulphuret potass. liquid. ℥j., Aq. pur. ℔ss. M. ft. lotio., or ℞. Decoct. althæ. off., ℔j. Liq. plumbi diacet. ℨj. M. ft. lotio. should be prescribed. Other lotions may be employed with the intent of removing the scales which cover the skin in pityriasis, psoriasis, or eczema squamosa; of cleansing the skin of the fatty layer which covers it, as in acne sebacea, or of causing the yellow spots and the mealy exfoliation covering them, as in pityriasis versicolor, to disappear; the natural or artificial sulphurous waters, or the alcaline solutions are the most useful in these cases. As a remedy for the itching which accompanies several cutaneous affections, and which is sometimes intolerable, lotions with the infusum. folior. stramon., or infus. folior. hyosciam., or decoct. papaver. capsul., or R. Potass. sulphuret., ℥j., Aquæ. distill ℥x., or the liniment recommended by Dr. Jadelot in the itch.[1] In chronic eczema with much itching, and especially in itching without an eruption. R. Cyanur. potass., grs. xij., Emulsion. amygdal. amar., ℥vij., ft. lotio. If the itching persists, notwithstanding these measures, R. Aq. distill. lactuc viros. ℔j., Aq. camphor ℥j. M. ft. lot. vel Bichlorid. hydrargyr. grs. iv., Aquæ distillat., ℥vij., Alcohol. menth. off. ℥ss. vel. R. Bichlorid. hydrargyr. grs. vj., Aquæ distillatæ ℔j. Rad. anchus. tinctor. ℨj. (this constitutes the celebrated *eau rouge* of the Hospital St. Louis, so praised by Alibert) pro dos. ℥j. ad ℥ij., vel. R. Bichlorid. hydrargyr. grs. xij., Aquæ distill. ℔ij., Alcohol. rectif. ℥vij., Camphor ℨss., ft. lotio, mane nocteque utend. No lotions are of much utility in exanthemata, with the exception of erysipelas, in which emollient or discutient lotions have been recommended, and in traumatic erysipelas in which astringent lotions are useful; in eczema they are useless, except when chronic, and then alcaline lotions and those containing mercury may be had recourse to. In psora, R. Ol. rosmarin off., Ol. lavandul. ver., Ol. menth. pip. āā ℈j., Alcohol. rectif. ℥vij. Infus. thym. ℔ij., ft. lotio. ℥iv. mane nocteque utend. vel. R. Iodid. sulph., Iodid. potass., āā ℨiss., Aq. puræ., ℔ij. ft. lotio. M. Soubeiran proposed replacing this last by a solution of iodide of potassium, with an addition of iodine; but repeated trials have proved that it is not so efficacious as when sulphur is present. Care must be taken not to prepare it too long, and to shake the bottle well, before its employment. In pustular eruptions, the only one in which lotions may be advantageously employed is impetigo, after the scabs have been detached. Lotions are useful in acne; in sycosis, they must be emollient, aromatic, or alcaline, according to the species or the state of the eruption. In porrigo favosa, Barlow's lotion, which may be followed by the solution of a chloruret when the scabs are detached. The ephelides and pityriasis versicolor are the only affections characterised by a change of colour of the skin, which can be affected by lotions, such as solutions of the chlorides or of the sulphurets. Finally, in psoriasis and lepra vulgaris, they must be applied conjointly with ointments. In all diseases of the skin, lotions and ointments must be considered as accessory measures.—*(Annales des Maladies de la Peau.)*

Fractures of the Acromion. Two cases of this fracture, with the *post mortem* examinations, were communicated by Dr. Nelaton, and inserted in the last number of the *Journal de Chirurgie*. Since this accident was observed for the first time, in the 17th century, not more than twelve cases have been recorded, and they are far from presenting all the authenticity to be desired; besides which, the symptoms of treatment[2] were founded on theoretical, rather than practical, deductions; and on this account, render the two cases about to be related, doubly interesting. Case 1st.—R., a day-labourer, ætat. 27, fell, while tipsy, from a first floor window; and was brought immediately to the Hospital des Cliniques, and placed in the wards of Professor J. Cloquet, then under the care of Dr Nelaton. In addition to symptoms of concussion of the brain, there was a deformity of the shoulder, which drew the attention of the *interne*, who diagnosticated luxation of the humerus, and proceeded to perform reduction, which, after failing the first time, on a second trial appeared to have succeeded. On examination the next morning, no signs of luxation were present, and the cerebral affection alone was attended to; it, however, in spite of the most energetic treatment, terminated fatally, two days after the accident. *Autopsy.*—As it was impossible to reproduce the luxation, the shoulder was carefully dissected; the muscles, tendons, and capsular ligament were found to be perfectly sound, the only lesion being a fracture of the acromion. This fracture was almost straight, and situated at about an inch from the summit of the process; the periosteum superiorly was partially torn, inferiorly, it was quite entire, so that the only possible change of position that could be obtained was the lowering of the extremity of the fragment. Case 2d.—Bonnet, ætat. 75, strong and hale for his age, entered the sick wards of Bicêtre on the 20th February, 1843. The only information that could be obtained from this man, whose intellectual faculties were rather dull, was, that while crossing Austerlitz bridge, he fell on the pavement. The right shoulder was considerably deformed, owing to an old fracture of the clavicle, which was very irregularly united. The lesions caused by the late fall were—1°. Two phlyctenæ, full of serosity on the inferior part of the dorsal surface, of the right forearm. 2°. A thick, black, firm, oval escar, about 4½ inches in length, and 3½ in breadth, similar to a burn in the third or fourth stage, on the anterior surface of the right knee. 3°. Finally, on examining the right scapula, a depression was found at the base of the acromion, in which the tip of the finger could be placed, and the two fragments could easily be made to move on each other by seizing the acromion in the right hand, and the scapula in the left; *head and arm not in the least altered from their normal position; all the movements in the shoulder and arm as if no accident had occurred; no pain, nor crepitus*; when the arm was carried forwards, the acromion followed the movements of the external extremity of the clavicle, and, at the same time, the distance between the two fragments was increased so as to admit two fingers; on the contrary, it diminished when the arm was carried backwards and outwards; in all these various movements, the acromion did not change its normal direction; ecchymosis extended from the seat of the fracture to the axilla, and from thence, along the inner side of the arm to the elbow; distance between the acromion and the external condyle was, on the right side, about 11¾ inches; on the left side, nearly 12½ inches. Mayor's triangular bandage for fractures of the clavicle was put on, and poultices were applied to the knee. The patient was very unruly, and removed the bandage every day, notwitstanding all the care with which it was applied, so that on the 27th February, as he complained of no pain whatever on free motion of the arm, it was taken off entirely, and the treatment was directed solely to the lesion of the knee; owing to the indocility of the patient, this became much aggravated; the synovial membrane burst, diarrhœa supervened, and death finally closed the scene on the 20th April, at 8 P.M., sixty days after the accident. *Autopsy.*—Right shoulder, acromion fractured transversely at its base, and about a finger's breadth distant from the spine of the scapula, the part corresponding to which, offered a sharp edge, formed by the under part of the bone; acromion united to the rest of the bone by a newly-formed fibrous band, as large as the surface of the fracture, composed of fibres, parallel to each other, extending from one surface to the other, and by the fibres of the deltoid and trapezius muscles, which were, in a measure, separated into two parts, the one attached to the acromion, and the other to the spine of the scapula; the edges of the capsule of the scapulo-humeral articulation were torn from the anatomical neck of the humerus for about four lines, opposite the insertion of the supra-spinatus, which was detached from the bone at the precise spot of its insertion, without removing any portion of the bone, or leaving any of its tendon; a probe introduced at this spot, did not penetrate the articulation. The patella was softened and redder than in its normal condition.

[1] *Linimentum saponis hydrosulphuretum.* (Jadelot's liniment) R. Saponis ℔j., Ol. semin. papaver. somnifer. ℔ij., Pulv. sulphur potass. ℥iij. ft. linimentum.

[2] Speaking of this fracture, S. Cooper (Dict. Pract. Surgery) expresses himself thus:—"When the acromion is broken, the weight of the arm, and the contraction of the deltoid muscle, draw it downward, while the trapezius, and levator scapulæ draw the rest of the bone upward and backward." "Fractures of the acromion are attended with *pain, which is increased by the motion of the arm; the form of the shoulder is changed;* and the broken part, which has descended, may be raised, by bringing up the elbow close to the side." "The fractured acromion requires the arm to be raised, that the head of the os brachii will push up the acromion, while an assistant pushes the scapula forward and downward, in a contrary direction to that of the arm. To maintain this position, a circular bandage is to be applied round the arm and body.

Spermatorrhœa.—A young man, about 26 years old, of tolerable constitution, was reduced to a mere

skeleton, and to an extreme state of pallidity and weakness, owing to nocturnal pollutions, of which he had from five to six every night; his appetite was lost; his intellect diminished, and his skin dry and harsh. Several means having been uselessly employed, not only before, but also since, his admission into Dr. Robert's ward at Beaujon Hospital, the cauterisation of the urethra not excepted, Dr. Roguetta asked Dr. Roberts to try secale cornutum, having had a case in his practice several years ago, in which, through its influence *alone* (in the present instance cauterisation was employed, in addition to the ergot of rye), a cure was obtained; consequently, the following pills were ordered:—R. secal. cornut. ℈ij., Camphor ℈j., Alcohol. rectif. q. s., pilulæ No. xx., quarum sumat. i., mane et nocte. Soon after their administration he loss of semen diminished, and gradually ceased; the patient gained strength and flesh, and ultimately recovered completely. The efficacy of the pills was undoubted, as if the patient ceased their use a day in the commencement of the treatment, the affection was aggravated.—(*Annales de Therapeutique.*)

Academy of Sciences; Sitting of the 30th June—M. E. de Beaumont in the chair.—At the *Comité Secret*, which took place to-day, the Section for Medicine and Surgery presented the following list of candidates for the seat vacant by the death of Professor Breschet:—1° Dr. Lallemand; 2° Professor Gerdy; 3° Dr. Jobert de Lamballe; 4° Professors Berard and Blandin ex æquo; 5° Drs. Amussat and Bourgery. This classification, if report speaks truly, gave rise to a very animated discussion among the learned members, many of whom expressed their surprise and dissatisfaction at seeing Professor Gerdy placed so high on the list, when Dr. Amussat was among the last, and a learned chemist added, he trusted it would, in the present instance, be in the Academy as in the kingdom of Heaven, where, as the Gospel says, the first are last, and the last first. Might not this mode of classification be adopted to ensure the nomination of the learned professor placed at the head of the list, by putting next to him a competitor whose chances are not so considerable? A periodical, speaking of this subject, states, that the objections made find an echo in the public opinion, for if it be as surgeon that the choice is made, it is astonishing that Professor Gerdy should be preferred to Drs. Jobert de Lamballe, Amussat, Berard, and Blandin, and if it be as savant and anatomist, surely what he has done cannot be compared to the learned researches of Dr. Bourgery. Be this as it may, the election, which will probably take place on Monday next, will show how far these different surmises are correct.

On the Molecular Modification of the Essence of Turpentine; by Dr. Bouchardat.—After repeated trials in order to discover a good solvent for caoutchouc, the author concluded that the essence of turpentine after distillation was the best. The essence thus modified was of a slight yellowish colour; smell somewhat similar to that of thyme, oil of naphtha, and essence of turpentine; it was lighter than the original essence, for the density of the latter is 0·8736, and that of the former 0·8420; it boiled at 185° F., but the temperature soon rose to 310° F., where it remained stationary. On analysis its composition was found to be the same as the original essence; examined with the apparatus of polarisation, the rotatory motion was 33·23, whilst that of the latter was 28·83.

On the Physiological Effects of the Vapour of the Essence of Turpentine; by the same.—The only immediate symptom observed after remaining for five or six hours in an atmosphere impregnated with the vapour of the essence of turpentine, was slight cephalalgia; the pulse continued regular, the appetite normal. During the night other morbid symptoms appeared, such as insomnia, continual agitation, hot skin, pulse 86, micturition more or less difficult, urine offering the characteristic odour. The next day great weariness, sense of weight, and pain in the loins were felt. This state could not be attributed to any peculiar idiosyncrasy in the author, since fishes placed in water containing the essence offered symptoms somewhat similar; and if painters do not experience such effects, it is probably owing to their becoming inured by habit to the vapours of the drug.

On the Anthropology of French Africa; by M. Bory St. Vincent.—According to the author, the inhabitants of this part of Africa belong to three races—1° The *Atlantic*, or *Authertoni*, comprising the Kabyles, Moors, Berberes, are the aborigines of the country, partly inhabiting the towns and partly fortified villages. The head here presented was that of a Kabyle seized while preaching the revolt and instantly decapitated. The facial angle is the same as that of the European. The thickness of the bones and the proportions of the cavity are likewise the same; 2° *Adamiques*, vulgo *Bedouins;* the individual to whom the head belonged was killed in a skirmish. The facial angle is more acute; bones of the skull very thin; the depression at the bridge of the nose does not exist; the bones of the nose are longer than in the generality of races; 3° *Ethiopian;* the head is that of a bandit, native of Soudan, killed by the cut of a sabre. The facial angle is still more acute; the skull very thick, the upper maxillary bone being so prominent that the head resembles that of an ape; the features were those of a negro; the ossa narium very short, nearly horizontal, and retain separate traces of their exotic origin. The Jews are sometimes similar to the first, and at others to the second type. Finally, the author states that in a future communication he will furnish proofs—1° That there are not more than forty or fifty inhabitants to the square league from Tunis to Mogador; 2° That they may easily be civilised; 3° That they already begin to feel the difference between the French and Turkish dominations.

Academy of Medicine. Sitting of the 1st of July—M. Caventou in the chair.

Pellagra.—Dr. Hameau, practising at Teste (Gironde), writes claiming his right as to the discovery of pellagra in France. The description given lately of this affection does not differ in the least from that recorded by him long ago; he therefore is astonished that his name should have been omitted in the numerous communications made to the Academy on this subject.

Dr. Husson presented some remarks relative to pathological anatomy as studied at the beginning of the present æra by Corvisart. Dr. Rochoux stated that Corvisart never opened the bodies; this is not correct, for from 1795 to 1798, at which period I attended his clinical lectures, autopsies were performed; but previous to the researches of Prost and Broussais, the intestines were never opened. Dr. Merat asserted that while he was Corvisart's pupil, from 1801 to 1812 or 1813, the intestines were always opened and carefully examined.

Report on the National Correspondents; presented by Dr. Honoré.—This report gave rise to a very confused discussion, in which several members were heard. The conclusions finally adopted were—1° Every year, at the first sitting of the month of May, the *conseil d'administration* will consult the Academy whether any new correspondents should be nominated; 2° The commission must be named three months at least before the election, which will take place on the second sitting in January; 3° In the report the losses sustained by the Academy will be indicated, the departments in which they occurred, and the titles of each of the candidates given; 4° The list of candidates must be double that of the vacant places; 5° The nominations must be as much as possible in the different sections in proportion to the titular members.

Lithotrity in a case of encysted Calculus.—Dr. Segalas communicated the following case, in which, though it was very complicated, and offered dangerous symptoms, he had successfully performed lithotrity. He was obliged, in order to attain his end, to modify the *brise pierre* usually employed by him, and which he had presented in 1839 to the Academy. *Case.*—Baron C., formerly colonel in the artillery, ætat. 75; one thigh amputated; affected with an enormous bronchocele and a hernia; subject to frequent cerebral congestions and retention of urine, which rendered necessary the constant use of the catheter. To these lesions, intense pain in the bladder, with bloody and ropy urine, had been lately added. When called in, I ascertained, on examination, that a cartilaginous stricture of the urethra existed, that the bladder was very irritable, bled when touched with the catheter, and contained an immense calculus. Dr. Talon, the baron's physician, agreeing with me in opinion, lithotrity was decided upon, and in six sittings the calculus was crushed and extracted. The symptoms, however, persisted; the bladder was explored anew with great care, and the presence of a second calculus, contained in a sac with a very narrow opening, was detected; its extraction was fruitlessly attempted; the attempt to crush it *in situ* with the ordinary *brise pierre* likewise failed, for, though I easily succeeded in introducing the instrument between the calculus and the walls of the sac, yet I was unable to seize it between the branches of the *brise pierre*. I, therefore, cut off half of the male branch, and by this means was enabled to remove small portions from the surface of the calculus. It thus became small enough, after numerous trials repeated weekly, to escape from the sac; it was then crushed, and the portions extracted in a very few sittings, after which the urine was no longer bloody. A catarrhal affection of the bladder which existed, was treated advantageously by injections of a solution of azotate of silver, and now the baron is as well as can be expected for his time of life.

GARLAND DE BEAUMONT, D.M.P., B.L. & S., &c.
Honorary Physician to the Spanish Embassy.

PROGRESS OF GERMAN MEDICAL SCIENCE.

By SIGISMUND SUTRO, M.D.

On the Cyanide of Potassium.—The author first refers to the different modes of preparation which influence the internal properties of the remedy. To prepare cyanide of potassium four different methods are enumerated, and it is shown by analysis that the mode of its preparation is a highly important matter for consideration during its employment. The solution of the purest cyanide of potassium undergoes rapid decomposition, and the salt prepared according to Wigger's method, and dissolved when required for use, is the best form for its adminstration. It is very useful as an external application, for those who employ nitrate of silver, or solutions of gold or platina, inasmuch as it quickly removes the black, violet, or brown spots produced on the skin by those bodies, in consequence of its property of dissolving their salts. For *pharmaceutical* purposes, such as the preparation of prussic acid, *Liebig's* cyanide of potassium is the most useful, as it furnishes a greater quantity (if the distillation proceeds easily) than the ferro-cyanate of potassium. The use of Liebig's cyanide of potassium for the purposes of art, such as galvanic silvering, gilding, &c., is well known.—(*Dr. Netwald in Oesterr. Wochenschr.*)

On the Use of Frictions with Oil, in the Treatment of the Diseases of Children.—The author, after a lucid introduction, refers to the employment of oil (which has been recommended as a specific by Baur) in scrofula. If we wish to explain the direct effect of remedies on the parenchymo-plasma, the physiological process of digestion must be first considered. It is proved by Purkinje that the albuminous aliments are dissolved by the muriatic acid contained in the gastric juice, and transformed into an albuminous acid chyme, which becomes alcalinescent in the duodenum by mixture with the bile and pancreatic juice, and completely loses its free acid in the chyliferous vessels, arriving at the mesenteric absorbents as a neutral fluid. In these vessels the chyle obtains its peculiar granular formation. It is further established, that the nerves materially influence normal chymification, whilst all further processes must be considered as hypothetical, it being only probable that cells are formed out of the albumen, fibrine, and fat of the blood destined to supply the different tissues (composed, therefore, of different constituents), and excreted at a later period as consumed and dissolved matter. The contact of the albumen of the blood with the liquid fat of the blood-corpuscles is perhaps the base of organic metamorphoses. But this process is subjected to very many alterations in the first years of infancy; thus laying the foundation of many diseases, such as scrofula, tabes, rachitis, disorders of the digestive apparatus, &c. These are based on a disproportion between the gastric and duodenal digestions, with disordered innervation and exsudation. This disproportion *either* proceeds from an

incomplete or an irregular chymification, caused by a slight degree of acidity of the gastric juice, *or* by a disturbed equilibrium between the chyme and the alcalinescent properties of the duodenal contents, by which means the acid re-action prevails, causing the albumen to coagulate; *or* from an irregular excretion; *or* from a defective pulmonary excretion of carbonic acid in consequence of organic diseases, inspiration of impure air, &c. This explains the frequent occurrence of diseases in some children, in spite of the best dietetic observances, and the unaltered health of others, which are subjected to injurious influences. If nurses labour frequently under mental excitement the milk becomes exceedingly acid, disturbing the digestive process, and predisposing the infant to tabes. Too profuse a secretion of gastric juice produces the same effect in weaned children, when they are fed on a too stimulating diet. Albumen, abnormally coagulated, can as well be introduced into the chyliferous vessels as mercurial molecules into the pores of the skin. The ready stagnation of coagulated liquids in the glands and absorbents is explained by the laws of endosmosis and exosmosis, and by the slow course which the chyle takes in the dense net of the anastomosing lymphatics of the mesentery. The author then proceeds to the consideration of the important question—"How does a remedy act on the blood and nervous system when it reaches the animal fluids, by being absorbed through the veins or lymphatics, and how do changes in the blood influence the organic process of reproduction?"—and he refers to a former article. According to Baur and the author's observations, frictions of the whole body with oil (linseed oil), till its absorption diminishes or ceases (which takes place after fifteen to twenty-four frictions), decidedly cures scrofula, tabes, and spasms, caused by functional disorders of the digestive organs, considerably aiding the growth and general strength. The oil is absorbed by endosmosis, without immediately reaching the blood through the veins. When imbibed, it combines with the albumen of the plastic constituents to form cells, which pass into the veins and serve for the nutrition of the body. These diseases being caused by obstruction of coagulated albumen in the glands, mucous membranes, bones, &c., in consequence of excessive acidity of the chyme, and incomplete alcalinescence of the biliary fat, the oil is destined to supply the latter by cellular formation. The plastic functions are thus increased, excretion of the deposited substances through the skin and kidneys is promoted, abnormal irritation of the nervous system is removed, and thus the equilibrium of the digestive organs is restored. The effect on the nervous system can only be considered as secondary, notwithstanding the tranquillity and sleep which generally follow the frictions, and which must be accounted for by the mechanical effects on the extremities of the nerves. As regards the indications, &c., the author perfectly coincides with Baur. After a warm bath (once a-day) the children are laid on a linen cloth, and rubbed with a tablespoonful of warmed linseed, poppy, or cod-liver oil, all over the body, with the exception of the head, then wrapped up in flannel, and laid in bed for a few hours. When the remedy ceases to be absorbed, which may be known by the oil remaining on the skin for several hours, before the disease is cured, the application of the oil should cease for a week or fortnight, and then be resumed. The author concludes his valuable treatise by the details of numerous interesting cases.—*(Dr. Röden, of Schweinfurt, in Bayer, Correspond. blatt.)*

Some observations on the effects of nitrate of potash.—In a treatise by M. Keller, the question is asked, why do nitrate and chlorate of potash operate as antiphlogistics? Each contains six atoms of oxygen; thus the temperature of the body ought to be increased by the combustion of the carbon and hydrogen of the blood, but, on the contrary, these remedies have a cooling effect. The heightened temperature in inflammatory diseases proceeds, however (*a*), from a want of oxygen, by which means less carbon and hydrogen are burnt; that is, withdrawn from the body in the form of carbonic acid and water, by means of expiration, evaporation, and urinary secretion. On this account, these remedies abstract from the body the excess of heat; (*b*) from the more rapid circulation of the blood (fever), which shows a tendency of nature to procure more oxygen; this reaction alone sometimes restores the equilibrium. But where the force of nature does not suffice, salts containing much oxygen must have a beneficial effect; for their oxygen combines with the substances unfit for further use, carbon and hydrogen are again properly excreted, and the temperature is lowered, where no structural decomposition (pus, effusion, &c.) has yet taken place, the equilibrium between the heat generated and that given off is restored, and the plasticity of the blood diminished. At the same time there should be strict attention to diet, in order to prevent the supply of fresh injurious substances, and venesection should be had recourse to for the removal of those matters which can no longer be liquefied. Keller shows the above views, as regards the fact of inflammation generally being based on a passive stagnation in the capillary vessels, to be correct. Thus, besides calomel, which removes hydruret of carbon by increased biliary secretion, and besides the vegetable acids, which partly arterialise the blood by giving off oxygen, and partly stimulate the ganglionic system by means of direct contact, thus affecting the functions of the heart and increasing the elimination of carbonic acid from the lungs, nitrate of potash forms an important auxiliary in the treatment of inflammation. Nitrate of potash is so decomposed in the stomach by the electricity always developing itself in that organ, that it is transformed into a lactate, or muriate of potash, whilst a considerable proportion of its pure oxygen is certainly disengaged from the nitric acid. Oxygen may be considered as the pabulum vitæ of the splanchnic nervous system, strengthening its tone and diminishing its increased action. Thus, in venous congestion, nitrate of potash may be as useful as in excessive arterial action. The effect of the oxygen is supported by the above mild salts of potash, which operate as diluents and emollients on the biliary system, the intestinal mucous membrane, and the kidneys. Nitre only exerts injurious effects when administered in too large doses. The essential influence of its oxygen in the operation of the remedy is proved by the circumstance that no other neutral salt can be effectually substituted. Where, however, nitrate of potash appears to act too energetically, nitrate of soda may be employed with great advantage.—*(Dr. Nickels, ibid.)*

State of patients who have undergone hydropathic treatment.—The patients who have not been cured by hydropathic treatment exhibit symptoms of a morbid state resembling the milder forms of scurvy, or rather aphthous ulceration. The pulse is unusually accelerated and weak, as if preceding a fever or chlorosis, and this particularly in the morning and evening, and at midday; occasional palpitations of the heart; pale urine, soon assuming an offensive smell; aphthæ and small ulcers in the mouth and throat; loss of appetite; great restlessness and unusual irritability. Leech-bites bleed very freely, and the gums are liable to spontaneous hæmorrhage. *(Dr. Albers, of Bonn, in Rhein, ad Westphal. Correspond.)*

On the use of unguentum acetatis plumbi in scalds.—If applied immediately after scalding, the ointment prevents the formation of blisters, relieves the pain, and diminishes the redness and swelling; in the cases where blisters are already formed, cicatrisation is soon effected after the fluid is discharged. The author never saw any injury arise from the employment of this remedy. He concludes by communicating two cases confirmatory of his statement.—*(Dr. Grosskopf un Oestreich, Medic Wochenschrift.)*

THE UNIVERSITY OF EDINBURGH AS A MEDICAL SCHOOL IN 1845.

To the Editor of the "Medical Times."

SIR,—It seems to be a fact pretty clearly admitted that the Premier has taken up a strong predilection for the system of the present Scotch Colleges, or, at least, for a modification of them, and that he intends giving to this system, be it good, or be it bad, the whole weight of his power. Nay, what is more, it is said that he intends extending the system to Ireland, and ultimately perhaps to England. Thinking men might be disposed to say, "Had you not better first ascertain how the system has worked? how educational institutions have thriven where the pedagogue and teacher occupied the position of the professor? Have any of them sunk to mere diploma shops not over respectable? Have men of genius and of European reputation found a ready access to the chairs?"

Two kinds of statistics on which to base an opinion may be collected, but it does not follow that either kind might be acceptable to the Premier. It might first be inquired into by figures, 1st, Whether or not the holders of chairs had not gradually sunk from first-rate men to second, third, or even fourth rates; 2nd, Whether it was, or was not, a fact that family arrangements, aided by local influence, had not acted so as to exclude all talent; however elevated; 3rd, As applied to actual existing institutions, whether it had, or had not, happened that such persons as Brewster, Faraday, Davy, Brown, Abercrombie, and others, had been distinctly refused a place within their walls? Or the inquiry into the working of the present Scotch collegiate system (with its London imitations) might assume another form—the scientific works produced by the establishment. Suppose the question put is: What do you know of the University of Heidelberg? Is it a celebrated school? Do they issue many diplomas? Do they do "much" business in that way? Our answer would be this: Heidelberg has produced, and now possesses, as its professors, some of the most distinguished scientific men and distinguished scholars the world can boast of; in this way do we value Heidelberg; in this way do we value Berlin; in this way do we value Paris; this made Leyden what it was; and the absence of these since the advent of the Dutch king makes it what it is. We are quite sensible that these are not the statistics which the Premier is looking for; twelve respectable fat-headed blockheads will perfectly suit him, and adequately and respectably, with a delightful and trustworthy mediocrity, fulfil "all the duties attached to the chairs that they have the honour to hold." This is the language of such distinguished wiseacres; having no reputation nor honour in themselves, they draw it from the "offices they have the honour to hold."

When Gottingen is mentioned we think of Haller; when Leyden, of Albinus; it was Scarpa who in latter days honoured an obscure Italian school by his presence. He was desirous of improving that school, and accordingly he suggested certain improvements to the Austrian Government. But in Metternich and in the thick-headed Francis he encountered a Sir Robert Peel, and a trading, shop-keeping oligarchy—contemners of all science and scientific men. "We want good, not great men," was the Austrian monarch's reply. "We want men of an orthodox mediocrity," is our present Premier's.

By a few very plain statements may the whole system be understood. During the last thirty years there has not issued from the chemical laboratories of Edinburgh or Glasgow a single original analysis; from the anatomical establishment, not a single original discovery. In Glasgow the names of the professors may be seen attached to the advertising cards of common grinders, a set of men who have all but ruined the medical profession. Two general practitioners occupy the chairs of surgery. In an establishment founded in London on the Scotch system, one of the professors of anatomy and physiology is not, nor ever was, a medical man, in any sense of the term. Lastly, the value of the diploma in the very first of these Scotch establishments has sunk so miserably that even St. Andrew's, the notorious St. Andrew's, now drives so very thriving a diploma trade that the sale of the Edinburgh parchment is fairly at a discount, and may speedily be all but extinguished. Yet this is the system which the Premier proposes inflicting on the Irish people!

Yet it must not be said that no works have proceeded from these establishments during the last forty years. Some have unquestionably. A review of the leading ones may at the present moment prove interesting to those who would like to see how the system has worked, and how it is sure to continue to work. With this view we shall select a few of the productions of chair-holders in these distinguished colleges—institutions of so doubtful a character that Kohl knew not exactly what name to give them. He thought them inferior to the

High Schools of Germany; and so they are, by many degrees. Surely there can be no injustice or unfairness in judging of them by their works!

Schlegel's Essay on the Physiognomy of Serpents. Translated by THOMAS STEWART TRAILL, M.D., F.R.S., Regius Professor, &c. in the University of Edinburgh.

Serpents, whether in a human or brute form, are unquestionably the most deservedly and most cordially hated of all God's creatures. Nothing pleasing, nothing popular, can be written respecting them; the encouragement of the brute breed would be madness or worse. The human serpent will probably multiply until the end of time, or at least until the advent of the millenium, when the great serpent is to be chained down to the bottom of the bottomless pit. In respect of the brute serpents treated of by the learned ophiologist Schlegel, whose work has been translated by the learned encyclopedist Dr. Traill, nothing short of their total extermination will ever please humanity. Who would trust a serpent—a snake in the grass? Do not trust to his being innoxious. Make by his death "security doubly sure, and take a bond of fate." Yet here they are as part and parcel of the existing order of things so well devised for the use of man, and therefore we do not complain nor declaim against their creation; but examine briefly their natural history as it has been given us by Schlegel, or rather the abridgment thereof by Dr. Traill, hoping that the day may arrive when the class of brute ophideans ceasing to exist, their remains may form a new chapter in the "osseous fossils" of some future Cuvier.

The history of serpents is a very curious history, of great antiquity and of vast extent, requiring much biblical learning, and much research. Dr. Traill has not handled this part of the subject with that book learning and book inquiry we were led to expect from so successful an encyclopedist. He has, we believe, written "Memoirs on Babylonish Bricks," "On the Hieroglyphic Writings on the Pyramids of Egypt;" "The Food of the Honey Bird" which does not Eat Honey; "The Small-Pox;" "The Chimpanzee;" "The Fine Arts;" "The Apollo;" &c. is at once the chemist, the physician, the clinical professor, the medical jurist, the naturalist, the practical accoucheur, the natural philosopher, the comparative anatomist! So that it might be said that if he but knew a little of medicine in reality, and of that art on which medicine is founded, namely human anatomy, the Doctor might be said to know something of everything

The "Physiognomy" of Serpents is Schlegel's term, and the German defends the use, or rather the abuse, of the term; for it clearly is an abuse when applied to the brute serpent, but an excellent phrase when tried upon the human reptile, with many of whom the learned in Edinburgh must by this time be tolerably acquainted. How it may be in the Low Countries, where the learned Schlegel resides, we know not. Human serpents there are no doubt in the Netherlands, and their general physiognomy will be known to the natives. Woe to them that have not this art.

Surprised and disappointed at the neglect of the human serpent evident throughout this translation of Schlegel, turn we next to the natural history of the brute serpent, as treated by Schlegel and his Arcadian translator. And here, at starting, we cannot but express an opinion or conjecture that the whole object of the volume has merely been to advertise the following fact, first stated in the preface, and which therefore might have been done at much less cost, for that any one will ever purchase a copy of this work on ophideans, is what neither the translator nor his publishers can ever hope for. The fact wished to be advertised is this:

"The translator has therefore restricted himself to the general portion of the work, and has selected from the excellent plates of his author twenty-four figures, each illustrative of one of the genera, to which he has added two figures, for explaining the modern terminology of the scuta that defend the heads of serpents, and likewise two others of a remarkable species of *Elaps*, first described by him in Jameson's "Edinburgh Philosophical Journal," for 1843. The specimen of this Elaps in his own collection the translator believed to be unique, as his correspondence with M. Schlegel shows that it was unknown to that great ophiologist; but on lately visiting the large and now well preserved zoological collection in the British Museum, he found one other specimen, though mutilated and without any indication of its native country."

Now this we believe to be the whole object of the present publication; the Doctor had the good fortune to stumble on a hitherto unnoticed specimen of the Elaps!

Let us now examine briefly the work itself, which consists of a map, the translator's preface, the author's preface, the introductory letter, and the body of the work itself. That both the author and translator have, generally speaking, merely seen serpents in cabinets is quite true; but Schlegel is a learned and honest man, so also is his translator; if we cannot call them observers, they at least are good compilers. We have already alluded to the translator's preface, and explained the whole object of the work. The Doctor knows nothing practically of serpents, but the *words* of science he handles bravely, like his brother jurist, Saturnine B—. M. Schlegel begins by defending the term physiognomy, though he is far from successful; he after all merely means "*all the natural characters and the result which a careful contemplation of them produces on the mind.*" *The Natural History* of Serpents is the proper title of the work. He complains, and with justice, no doubt, of his predecessors, and their inaccuracies, and he endeavours rigorously to determine all the known species. We quote a passage explanatory of the source of many errors in natural history, and of which some amusing instances have come to our knowledge. Men who have not been early educated as scientific men, pay not in general the smallest regard to truth in scientific matters.

"It is also necessary to use circumspection in consulting the intimations of the native place of animals, as they are given in most works. Few naturalists have the opportunity of obtaining these objects at the first hand, and we can rarely trust to the veracity of mariners who, often deceived themselves, bring back in their voyages objects of natural history from distant countries which they have visited." The mistakes they commit are endless, and ridiculous, no doubt; we ourselves have seen much of this. A single passage will show to what vexations naturalists are exposed by coarse errors of this kind. "One of my friends (p. 7.) accepting the offer of an emigrant to the United States, to make collections of Natural History, furnished him with the means of making his first consignment. This consignment arrived; it contained a collection of the reptiles of the Cape of Good Hope."

Some judicious and excellent ideas are given by M. Schlegel, as to what iconographic representations should be; these are worthy of all attention on the part of travellers. But our object is not an elaborate critique on the work of M. Schlegel (which is not now before us), but a mere notice to prove that the ministerial pocket corporations, called Scotch colleges, are filled by Daws, as they were originally termed by that most worthy man, and respected elder, of the so-called kirk, the late Dr. John Barclay: and that the mutilation of M. Schlegel's work, by Dr. Traill, proves him to belong to the fraternity.

Now all this may be done in a dozen words; for from the beginning to the end of the work there is not a single original observation which can be traced to the worthy translator. What a pity it is that he joined these Daws! Here was an honest man and a kind-hearted gentleman spoiled by their corporate influence.

There is a statement made by M. Schlegel, which would require the most extensive proof, namely, that "the number of vertebræ differ in serpents of the same species, some thirty or forty, more or less." Return to the structure again, M. Schlegel, and we believe you will find yourself wrong with respect to that gland, the poison gland, and those poisoned teeth or fangs, which have rendered the serpent at all times an object of abhorrence to man. The observations of M. Schlegel, although based on extensive observation, do not seem altogether satisfactory: more especially as regards the pretended groove on the convex side of the tooth, said to be the precursor of the poison canal itself. This theory, for it is one, has not been satisfactorily proved, and it certainly does not exist in all; Rosa's description, as cited by Schlegel from Meckel, does not seem a correct or good one. These ideas of Rosa's had been disproved twenty years ago, in the very society in which the worthy Dr. Traill made his onslaught lately on a fellow member, when, to the horror of all present, the Doctor declared the whole doctrines of philosophic anatomy supported by Gœthe, Bojanus, Schwann, Frank, Geoffrey, De Blainville, and by all the real anatomists of the present day, to be "downright nonsense." Merciful powers! what was the astonishment of the young anatomists, and the old ones too, when they heard the alarming declaration. Had they but known the "Daws" so long as we have done, nothing of this kind would have surprised them.

Poisons are poisons only to certain animals; thus the viper's poison has no effect on shell fish or mollusca of any kind, nor animals that have no back bone; there must be something peculiar, then, in their nervous system. Still there is nothing, perhaps, after all, very remarkable in this; hemlock is not a poison to a goat. As we skim over the translation before us, an occasional remark or two occurs deserving especial notice, but exceedingly rarely, and rare by any chance from its translator, who had never indeed observed serpents, nor any thing else. It is well, for example, to know what animals are the natural enemies of all snakes; these seem to be the badger, the hedgehog, the weasel, the marten, and the polecat; verily, we shall never again wittingly destroy any of these most valuable inestimable animals; let us spare a little of our poultry for the preservation of these destroyers of the "grand enemy of mankind." Buzzards, kites, and crows also feed on snakes; but what appears singular is, that M. Schlegel denies the hog to be a destroyer of snakes, or to eat them; and he farther says that it is merely a prejudice and error to suppose so. Now against this opinion of the Dutchman, we have the statement of all Americans we have spoken with; they describe the hog as the determined enemy and destroyer of rattlesnakes, and that he eats them. This latter part of the statement is of little moment, provided it be but proved that the hog kills them; this is no trifling question, and we call on the American readers of this article to prove or disprove the fact.

Like most Dutchmen, M. Schlegel is slow of belief—he belongs to a rational and a protesting race—he denies the fascinating power of snakes. These and many other delightful stories our excellent Dutchman regards as pure fables, unworthy the attention of a scientific man.

A vulgar prejudice prevails, even here, in Britain, especially in Scotland, where the viper is sufficiently abundant, that it is *the sting* only of the viper which is dangerous, and not its teeth. But the viper has no sting; and what the vulgar, high and low, take for its sting is merely the animal's forked tongue, which it darts out when enraged.

It has been admitted by M. Schlegel at page 178, that there are venomous snakes scarcely, if at all, distinguishable from the harmless ones by any external appearance; therefore his *physiognomical* rule is of no avail. We knew this thirty years ago, and had thought that all who had travelled into hot countries were aware of it, and so M. Schlegel might have known it, and avoided giving to his work a ridiculous pedantic title. With all his boasted reference to external characters, M. Schlegel's arrangement of venomous serpents is based on the teeth, characters which can only be discovered after the death of the animal.

He divides them into three groups:—

1. Colubriform.
2. Hydrophis.
3. Venomous snakes properly so called.

The first, or Colubriform, he defines as snakes with solid teeth, on the maxillary bone in addition to the fangs; these are short and have grooves. Elaps, Burgarus, Naja.

II. The Sea Snake, or Hydrophis. Teeth as above; inhabit the tropical seas.

III. Venomous Snakes, par excellence. The fang is alone on the maxillary bone.

1. Trigono-Cephalus. 2. Crotalus. 3. Vipera.

When we took up this Treatise on Serpents we

could have risked any amount, on a wager, that the Doctor would find serpents in Arkney in one shape or another (by Arkney we mean Orkney, but as the Orcadians uniformly pronounce it Arkney, we suppose they must be in the right); it appears, however, from nearly the only note added by the translator to M. Schlegel's work, that there are no serpents in Orkney; at least, no live ones; but fossil ones may, perhaps, some day be found. The brute and human serpents seem to have come into the world, if not together, so at least as nearly to coincide: very few fossil snakes have been found, and, so far as we know, not a single complete specimen. Milton brings them in together, but I fear that the cautious Dutchman might not be inclined to take Milton as a trustworthy authority.

Return we now to the translator's preface; and as with it we commenced, so in it we shall find a portion of our argument, that a college of "Daws" must not only destroy all true science within its walls, but must prove the most efficient engine for crushing it every where. "He would willingly" (it is the Doctor who writes)—"he would willingly have published a translation of the complete work of M. Schlegel; but the *low state* of ophiology *in this country* deters any bookseller from undertaking so large a work on serpents." Excellent! low state of ophiology! why not say science? Can science exist with the highest educational institutions in the hands of those whose whole aim has been to crush its followers? Look at the museums! Have you not shut out all scientific men from the only museum in the country for nearly half a century? Low state of ophiology? Why, what is there which is high? Is it geology? Alas! Chemistry? The illustrious Hope is dead and gone; for forty years did this relater of the opinions and discoveries of others pass, with those who knew no better, for a scientific man. *Homo noster celeberrimus* is gone; he, to whom so many cowardly sycophants dedicated their theses to soothe and pacify him! He is gone; he to whom a friend of ours, a good anatomist and rather clear-headed man, laboured for three whole days to explain, that of the nerves of the face, there was one a motor nerve (the facial or portio dura), and the other a sentient nerve (the fifth pair), and failed signally; at the end of the third day, when asked by the addle-headed professor to state to him, after all, which really was the fifth and which the portio dura, the scalpel dropped from the hand of our friend, his jaw fell, and he remained for some time at least absolutely speechless. The discovery was too much for him; it nearly upset his intellect; here was a person, a medical professor (and he knew that most of his colleagues were in the same predicament), who could not be taught the very simplest fact in the anatomy or physiology of the human body! And this leads us to a consideration of the *anatomical school, i.e.*, the leading medical department in this same university, where the Homes, the Hopes, the Duncans taught, or pretended to teach; surely this may be also judged of by an examination of the anatomical work compiled and published by its anatomical professor; sanctioned by his colleagues, and constituting for the last twenty years the anatomical text book of the University of Edinburgh.

REPORTS ON DISEASES OF FEMALES.

By EDWARD RIGBY, M.D.

Fellow of the Royal College of Physicians, Senior Physician to the General Lying-in Hospital, Lecturer on Midwifery at St. Bartholomew's Hospital, Examiner on Midwifery to the University of London, &c.

(Continued from page 264.)

The simple leucorrhœa, as it appears in this country, is usually preceded and attended with much gastric atony, and general dyspepsia; there is that lassitude and inability of exertion which characterises this condition. The muscles are soft and flabby; the tongue large and pale; there is an unpleasant taste in the mouth, especially in the morning; the evacuations are unhealthy. The patient feels a dragging pain in her back and loins, which is increased on standing, but relieved or removed on assuming the horizontal posture. This results from a slight descent of the uterus, owing to the relaxed vagina no longer affording the necessary degree of support for maintaining it in its proper situation. Up to this period, the discharge has been purely mucous, without colour or smell, and becoming more thin and watery as it increased in quantity; but now that the uterus descends lower than usual into the vagina, its presence produces irritation there, and the discharge changes its character, becoming muco-purulent. Hence it is not always either possible or practical to define the precise limits between the simple and chronic forms of leucorrhœa, the one passing into the other by insensible degrees. Indeed, it is scarcely possible that simple leucorrhœa can exist to any extent for a considerable time, without having its characters more or less modified. The mechanical irritation produced by the slightly prolapsed uterus, is, perhaps, one of the most common and frequent causes; but, apart from this, the continued drain upon the system soon lowers its powers sufficiently to derange the functions of assimilation. The circulation becomes more or less vitiated, and the mucous membranes are among the first of the secreting organs to suffer.

In the early stages of the disease the indications for treatment are very simple, viz., merely to regulate the health, and support the tone of the system, by gentle alteratives and tonics, and to avoid those causes which have probably induced the complaint. The former will be assisted by using all the ordinary measures for invigorating the system, as the shower-bath, cold sponging, friction with horse-hair gloves, &c.; the latter will be effected by removing to a healthier locality, and breathing a purer air. The following cases may be taken as illustrations of the preceding remarks.

L. S., ætat. 21; tall, pale, and delicate-looking; unmarried.

January 15th, 1835.—Complains of cold feet, unrefreshing sleep, want of appetite, and pain of epigastrium; the bowels are confined; the pulse is weak; has constant leucorrhœa, with pain of back and loins, when in the erect posture; she is obliged to stand many hours a-day in a shop.

Applicetur sinapismus epigastrio.

℞. Pil. hydrarg. Extr. gentianæ, Extr. coloc. co. āā ℈j. M. ft. pil. xij. sumat. ij. o. n.

℞. Acidi nitrici dil. Tinct. hyosc. āā m. xv., Syrupi aurantii ʒii., Infus. gentianæ co. Aquæ menth. pip. āā ℥vss. M. ft. haustus bis die sumendus.

Under this treatment the pain of the epigastrium abated, the extremities became warm, the appetite improved, and the leucorrhœa disappeared without any local application; a restoration to a healthy tone of the system being sufficient to effect this object.

In about three months afterwards she returned, suffering severely from headache, and much gastric derangement; the leucorrhœa was as profuse as before. The same medicines were repeated, her health improved, but although she continued to take them for a month, the leucorrhœa did not entirely cease. She was, therefore, directed to use an injection of lotio plumbi, which checked the discharge, and I saw no more of her. This is the simplest form of injection which can be used in leucorrhœa, and which, when duly aided by general treatment, is usually quite sufficient for the purpose. If the disease be of longer standing, and accompanied with more or less vaginal irritation, the liq. plumbi diacet. may be advantageously combined with decoct. papaveris. In many cases of simple leucorrhœa it can scarcely be said that symptoms of prolapsus uteri exist, but in others the slight amount of it is sufficient to lay the foundation of much derangement. In the first place, by increasing the leucorrhœa it increases the relaxed condition of the vagina, and consequent descent of the uterus. The attachments of the uterus being put on the stretch, the returning circulation of the part is considerably impeded; the uterus swells, and grows heavier; by the first change it dilates the vagina still more; by the second its increased weight overpowers what little support the relaxed vagina is capable of affording it. Partial prolapsus is established, and the os and cervix, being the most depending parts of the uterus, and, therefore, the most disposed to vascular engorgement, become swollen, hard, and painful, with the various symptoms which I have already enumerated under the head of inflammation of these parts.

Simple leucorrhœa seldom exists for any length of time without the catamenia becoming more or less deranged; they are either sparing or absent, the system, from the continued leucorrhœal drain, not having wherewith to furnish the periodical discharge; or, on the other hand, where the uterine circulation has been much engorged, the catamenia appear either too frequently, or in too profuse a quantity, and thus is the leucorrhœal affection ultimately merged in the more prominent and urgent symptoms of those derangements which have arisen in consequence of it. I offer these observations in order to show that "simple leucorrhœa," however simple the affection may be, is one which demands attention, and ought never to be passed by as trivial, because it is quite capable of paving the way to affections of much more serious import, and which may ultimately break up the patient's health.

S M., ætat. 40; mother of one child.

Sept. 1st, 1835.—Complains of severe and constant pain of back and loins, with sensation of bearing down, which is considerably aggravated just before and during a menstrual period. Much leucorrhœa, the commencement of which she dates from a severe instrumental labour, which she had five years and a-half ago; during the last three years it has been of a yellowish colour, but it is within the last twelve months that she has suffered from pain of the back and loins, which has considerably increased of late; some gastric derangement; bowels open.

℞. Pil. hydrarg. chloridi co. gr. v., alternis noctibus.

℞. Acid. nitrici dil. Tinct. hyosc. āā m. xv., Syrupi aurant. ʒj., Infus. gentianæ co. ℥iss. M. ft. haust. bis die sumendus.

℞. Liq. plumbi diacet. Tinct. opii āā ʒij. Aquæ distillatæ ℥viij. M. ft. lotio.

8th.—Feels better in every respect; the bearing down pain is much better; the discharge is less. Pergat.

She ceased to attend until

December 1st.—Has returned with her former symptoms. Pergat.

15th.—Bowels confined; leucorrhœa continues unabated.

℞. Pil. hydrarg. Extr. coloc. co. āā gr. v. o. n. Rep. haustus.

℞. Magnes. sulph. ℥ss., Magnes. carb. gr. xv. ex. aq. menth. pip. o. m. ad tertiam vicem.

℞. Decoct. quercûs c. alumine.

M. H., ætat. 30; mother of one child.

December 15th, 1835.—Has much leucorrhœal discharge, with bearing down pain when she stands; no difficulty in passing urine or fæces; bowels confined; very slight gastric derangement. Was delivered five weeks ago by means of the short forceps; there is no laceration of the perineum.

℞. Extr. coloc. co. Extr. hyosc. āā gr. v. o. n.

℞. Haust. sennæ co. o. m.

℞. Liq. plumbi diacet. Tinct. opii āā ʒij, Aquæ distill. ℥vijss. M. ft. lotio.

22nd.—Feels better. Rep. pil. and lotio.

℞. Confect. sennæ o. m.

January 5th.—Health improved, but still has some discharge, and bearing down pain. Rep. pil. and confect.

℞. Decoct. quercûs c. alumine.

These two cases differ from the preceding, in not being the result of mere gastric atony and derangement, but of previous labour, which had been more than ordinarily severe and protracted. The probability is, that the vagina had never entirely recovered from the dilatation which it had undergone at that time, and being poor people, they had not been able to preserve the recumbent position afterwards so long as might have been desirable, but had assumed the erect posture when the uterus was still large and heavy, and before the vagina was sufficiently contracted to support it. In neither instances does it seem to have arisen from gastric derangement, the slight degree which existed being evidently the effect, not the cause, of the leucorrhœa.

In the first case, the discharge was of long standing, and had latterly assumed the chronic form; in the other, it was of much shorter duration; in both, there was evidently a slight descent of the uterus, as shown by the pain and bearing down, increased by the erect posture, and aggravated, in the first case, at the menstrual periods, from the local congestion rendering the uterus, at these times, larger

and heavier; but in neither did it go to any extent, there being no evidence that the bladder or rectum were pressed upon, which would have been the case if the prolapsus had been at all considerable. The treatment in both was essentially the same.

I could easily report other cases of a similar description, but those already detailed are sufficient to illustrate what I have said upon the subject. The following case is much of the same character, except that it was produced by a different cause, viz., that of nursing a child, when the patient's strength was unequal to the task.

S. G., ætat. 24; mother of one child.

January 26th, 1836.—Pale; fair complexion; complains of much headache, vertigo, and bad rest at night; the bowels are open, but there is much gastric derangement; has had leucorrhœa, with bearing down pain, since her confinement; is suckling her child, although she has not much milk.

℞. Acidi nitrici dil. Tinc. hyosc. āā M. xv. Infus. gentianæ co., Aquæ menthæ pip. āā ℥ss. M. ft. haust. bis die sumendus.

℞. Liq. plumbi diacet, Tinct. opii āā ʒij., Aquæ distill. ℥viijss. M. ft. lotio.

February 2nd.—Does not feel better; the leucorrhœa continues; she must wean her child. Omitt. lotio.

℞. Quinini disulph. gr. ij., Extr. hyosc. gr. v. M. ft. pil. ij. o. n. s.

℞. Decoct. quercus c. alumine. Rep. haustus.

16th.—Has weaned her child, and feels stronger, but still has many anomalous dyspeptic symptoms. Omitt. pilulæ.

℞. Pil. hydrarg. chloridi co. gr. v. o. n. Rep. alia.

23rd.—Feels much better in every respect. Omitt. pilulæ.

℞. Pil. ferri co. gr. v. o. n. Rep. haust. and lotio.

March 1st.—Improving. Pergat.

Nothing is more common than to see the simple form of leucorrhœa brought on where the strength of the patient is unequal to the task of nursing her child. It is frequently attended by a great number of nervous symptoms, arising from the state of exhaustion thus produced, and which I propose to consider under the separate head of "*Anæmia Lactantium.*"

The sub-acute form of leucorrhœa, commonly known by its white, creamy, or albuminous character, has been, in a great measure, already described, under the head of "Inflammation of the Os and Cervix Uteri." I, therefore, subjoin only one case in illustration of it.

M. A. M., ætat. 31; a widow; mother of six children.

June 23rd, 1835.—Complains of pain in her back and loins, with occasional difficulty in passing water; has severe pain in the middle of the pelvis, shooting along the groin and thighs, especially during the passage of a costive motion; bowels confined; gastric derangement; abdomen large; has a discharge from the vagina of a glutinous fluid, like cream in appearance. Has been subject to leucorrhœa for many years.

Vaginal Examination.—Os uteri rather swollen; cervix very painful; uterus feels large. On applying my finger to the cervix, I thought I could perceive it throb.

℞. Pil. hydrarg. Extr. gentianæ āā gr. v. o. n.

℞. Acidi nitrici dil. Tinct. hyosc. āā *m.* xv., Syrupi cimonum ʒj., Infus. gentianæ co., Aquæ menth. pip. āā ℥ss. M. ft. haust. bis die sumendus.

℞. Magnes. sulph. ℥ss., Magnes. carb. gr. xv. om. mane ex aq. menthæ pip.

30th.—Feels better, but has still some pain of her back and loins. Rep. Medicam.

℞. Liq. plumbi diacet. ʒij., Aquæ distill. Oj. M. ft. lotio.

July 27th.—Has continued to take the same medicines; she feels much stronger. The pain of back is less, and the discharge much diminished. This attack of leucorrhœa was evidently connected with inflammatory action of the os and cervix uteri, which yielded under a course of mild alterative, laxative, and tonic medicines. The discharge had probably been, in its earlier stages, nothing more than simple leucorrhœa, the lower, and consequently most depending, parts of the uterus gradually becoming congested and inflamed.

The leucorrhœa of early pregnancy is closely allied to the above species, and seems to be also the product of increased vascular action; in some cases this is not very perceptible, in others it is more distinct.

J. S., ætat. 25; mother of two children.

August 5th, 1836.—Complains of darting pains through the pelvis, coming on at intervals, with pain during the passage of fæces. Has a vaginal discharge, which is frequently creamy, sometimes albuminous, and sometimes yellow. Believes herself to be pregnant, and has observed the leucorrhœa from the supposed commencement of her pregnancy; complains of pain of limbs, and gastric derangement.

Vaginal Examination.—Os uteri closed and circular; one little hard spot is to be felt upon it, which is probably a cicatrix from her former labours; it is not painful.

℞. Extr. gentianæ, Extr. hyosc. āā gr. v. o. n.

℞. Magnes. sulph. ℥ss., Magnes. carb. gr. xv. o. m. ex aqua menthæ pip.

℞. Liq. plumbi diacet. Tinct. opii āā ʒij, Aquæ Oj. M. ft. lotio.

12th.—Feels better in every respect; discharge less. Pergat.

19th.—Continues to improve. Omitt. pil.

℞. Pil. ferri co. gr. v. o. n. Rep. alia.

26th.—Feels better in health, but complains of much weight at the lower part of the abdomen, which has distinctly and rapidly enlarged; bowels confined. Omitt. mist. salina.

℞. Pulv. jalapæ co. ℈j. o. m. Rep. alia.

Although the cessation of the catamenia is not mentioned in the report, the existence of pregnancy may, I think, be safely inferred, from the round and closed state of the os uteri, and subsequent enlargement of the abdomen.

Even where there is an entire absence of pain, with other symptoms indicating congestion, the discharge copious, and not having the white, creamy, albuminous character, it is not desirable to use locally any stronger astringent, if, indeed, it deserves that name at all, than the lotio plumbi; for by suddenly checking the discharge, at a time when there is such an increase of vascular activity in the uterine system, it might expose the patient to the risk of abortion. From the same reason saline laxatives are preferable, and by no means incompatible with the use of tonic medicines, if these be deemed necessary.

HOSPITAL REPORTS.

ST. THOMAS'S HOSPITAL.

Reported for the Medical Times by Alfred H. Cherry, Esq. Clapham Common.

Incipient Trismus.—Robert Larking, ætat. 23, pork-butcher, was admitted into William's ward, Nov. 13, 1844, under Mr. M'Murdo.

The patient is spare and of sickly appearance, but says he has always enjoyed good health. His statement is, that, three weeks since, he stuck a penknife into the muscular part of the left thumb, just below the base of the metacarpal bone, the knife taking a direction upwards; it bled very little at the time, and he did not think much of it. Two days afterwards it burst out, and bled a great deal (he says a quart); the wound then became swollen, painful, and discharged a little pus; he then poulticed it. It continued painful for about ten days, after which pain came on at intervals, but left him entirely about nine days since; he then felt his right arm rather rigid; three days afterwards he felt pain in the left side of the face and neck, accompanied with rigidity and difficulty of swallowing, which has continued increasing until the present time.

Present state.—There is a wound about half an inch long on the anterior part of the muscles of the thumb, partly healed, and discharging very little; it is not painful except when pressed; but he complains of great pain in the left side of the face and under the angle of the jaw, and also in the right temporal region; this is not constant, but there are frequent paroxysms. He cannot swallow any solid food, and it hurts him very much to take fluids; this has increased very much the last three days. He cannot open his mouth more than three-quarters of an inch; this, also, has become worse since yesterday. Complains of great pain in the bowels, which were freely relieved last night; has no rigidity or pain in any other part of the body; is not subject to spasms, nor did he ever have any convulsions. Tongue is coated with a thick white fur. Pulse 108, weak; has not slept for three nights. Mr. M'Murdo saw him, and ordered, Hydr. chl. gr. v. stat., Ol. ricini. posthor., Pulv. opii gr. ij. stat. et rep., hora somni et primo mane si opus sit. To have milk and beef-tea.

Nov. 14.—Slept badly; bowels open; has not so much pain in neck, face, nor abdomen, nor has he so much in swallowing, and he can open his mouth wider. Rep. Pulv. opii. gr. ii. ter in die.

15.—Slept well last night; can open his mouth wider, and has less pain, but still has great pain in right side of face.

16.—Sleeps well; can open his mouth better; and swallows with very little pain now. Tongue clean. Pulse 100, full, and weak; bowels open. Ordered: house diet, and beef-tea.

18.—Can now open his mouth to nearly its full extent; has no pain whatever; appetite good; bowels open; pulse weak. Ordered porter Oj., and meat daily.

20.—Has now not the slightest rigidity about the jaws whatever; can open his mouth, with ease, to its full extent; sleeps well; appetite good. The patient continued well for a few days, and left the hospital cured.

Tetanus.—James Bradon, æt. 42, lighterman, was admitted into George's ward, December 28th, 1843, under Mr. Green. His wife states, that on the 11th inst. he jammed his little finger, causing a penetrating wound near the nail; he afterwards went on with his work as usual. A few days afterwards, he felt a stiffness about the face and jaws, which increased so much, that on the 22d he was unable to take solid food, and the following day was obliged to relinquish his work, and continued getting worse until his admission.

Present state.—Jaws nearly closed, cannot be opened more than a quarter of an inch; has frequent spasmodic twitches of the muscles of face and neck, especially when an attempt is made to speak. When raised in his bed, his head is thrown backwards by the action of the muscles of the back. Has spasm also of the legs, thighs, muscles of back and abdomen—the former, however, predominating; has frequent and severe paroxysms of spasms, when he rests entirely on his occiput and heels; arms are not affected; complains of great pain in the epigastric region. Bowels much confined.

Mr. Solly saw him at 1 P.M., freely incised the finger, and ordered—Hydr. chl. grs. ij., Opii gr. ½, 4 tis horis. Enema terebinth. stat. Cataplasma sinapis epigastrio. Brandy ℥iv.

8 P.M.—Mr. Solly again saw him; his bowels had not been relieved, although he had had two enemas; he then ordered—Olei. croton. tig. gtt. ij., stat. and an enema of house medicine.

December 29th, 9 A.M.—Slept a little during the night, but is much the same to day. Bowels not open, has hiccough, also retention of urine, is therefore obliged to have the catheter introduced. Ordered—an enema tabaci. ʒss, ad ℥viij. aquæ.

10 P.M.—After the enema, had great prostration and profuse perspiration, but the paroxysms of spasm soon returned again, as violently as ever. He also took, during the afternoon, two more drops of the ol. tig. crot., after which, his bowels were freely relieved; he now says he is a little better. Ordered—Tinct. cannabis indic. *m.* xx., and increased with each dose, and at such times as the dresser should think proper, also a blister to be applied all down the spine.

30th, 10 A.M.—Took during the night, *m.* cxxx. of the tinct; patient dozed a little occasionally; spasm of throat, abdomen, and back rather less; bowels freely relieved three times this morning; passed his urine himself; pulse varies in number, but is weak; has hiccough occasionally. Takes beef-tea, arrowroot, milk, and brandy. Ordered—Vini rubri ℥iv.; gums tender. Omitte. hydr. chl.

10 P.M.—Spasm less; can open his mouth half an inch; swallows with less difficulty; bowels open; takes the tinct cannabis Indic. in *m.* xx. doses frequently.

31.—Not quite so well to-day. Bowels open; pulse varies; takes all his nourishment, also the tinct. in *m.* xx. doses. Sleeps occasionally for a

short time; but has frequent paroxysms of spasm; and perspires a great deal.

Jan. 1, 1844.—Is much the same as yesterday. Repetantur omnia.

2.—Bowels being rather confined; an enema of house medicine was administered, after which they acted freely. The spasms are very great; and the patient occasionally slightly delirious. During the morning had two enemas of tobacco, gr. xv; ad. ℥ viij aq.; but with no marked benefit. The paroxysms, which are very severe, come on about every quarter of an hour. He still continues the Tinct. cannab. indic.; and takes, besides, what was before ordered. Porter, Oj.

3.—Passed a better night; spasms less severe to-day; bowels open; takes his nourishment well. Omit all medicine.

4.—Slept a little during the night; spasms less severe; bowels open. Mr. Solly saw him at 10 A.M., and ordered Morph. mur. gr. ¼ st. at.; after taking which he slept for more than four hours.

6.—Much better; spasms less; sleeps better; bowels open. Takes the morphia at bed-time, but does not require it during the day.

8.—Improving; sleeps better; and spasms much less.

10.—Is much better; can move his legs now, and slightly flex them; can also open his mouth wider. To have ℥ ij more of wine, and a mutton chop pounded, so that he can drink it in his beef-tea.

13.—Continues improving; has no paroxysms of spasm now; sleeps well; bowels are open; but is obliged to take Mist. sennæ co., p. r. n. Takes all his nourishment well; takes gr. j of morphia at bed-time only.

17.—Patient can now sit up in bed and eat his mutton chop (not pounded); can also open his mouth much wider; sleeps well; appetite good; and has very little spasm now.

24.—Patient can now walk with the assistance of two sticks, and continues rapidly improving.

From this time he had no return of the spasms, and, although he remained in the hospital a long time (it not being considered safe to let him go out during the inclemency of the weather), he ultimately left the hospital perfectly well.

KING'S COLLEGE HOSPITAL.

Reported for the Medical Times by Evan Thomas, Esq., late House Surgeon to King's College Hospital.

Extensive Lacerated Wound of the Scalp, followed by Erysipelas—Death.

Elizabeth Watson, ætat. 75, is a kitchen-maid in the Temple; she is married, has had twelve children; of short stature, very stout, robust, and active; has always enjoyed very good health, and lived well, but of temperate habits; applied as an out-patient at King's College Hospital, under the care of Mr. Partridge, on the 2nd of September. Shortly before (her application) she accidentally fell down a flight of stairs, her head coming against one of the steps; she was sober when the accident happened. Upon examination, a lacerated wound, about eleven inches, was found on the right side of the head, commencing half an inch above the zygoma, extending for some distance vertically upwards, then taking somewhat the direction of the temporal ridge, and continuing as far back as the occipital protuberance; the lower edge of the wound had been dragged about two inches apart from the other; the tendon of the occipito frontalis was unevenly torn, but the bone was not exposed in any part; very little bleeding followed. The hair surrounding the wound was shaved, and the rest of the hair cut close to the integuments; the edges of the wound were next brought into apposition by broad strips of adhesive plaister, taking the precaution to allow spaces for the escape of the discharge; the whole of the scalp was ordered to be kept constantly wet with goulard water. ℞. Spt. ammon. aromat. m. xxx., Mist. camphoræ ℥j M. 4tis horis.

Sept. 3.—She was seen to-day by the house-surgeon at her own home (as she had refused to be admitted when she first applied); she had had no shivering, nor much pain in the head; there was a good deal of tenderness on the right side of the scalp below the wound, but there was no swelling; a little thirsty, appetite pretty good; pulse 80, regular, respiration natural. She was ordered to continue the ammonia three times a-day, a little wine, arrow root, and beef-tea.

4.—Had a shivering fit last night, which continued for half an hour; complains of general headache and great tenderness about the wound, and generally over the scalp; is thirsty; appetite not so good as yesterday; pulse 90, feeble; tongue dry, brown, and furred. Continue the wine, arrow-root, and beef-tea, as much as she can take; continue the ammonia every four hours; fomentations of hot water continually applied to the head and face, which is also a little painful.

5.—Was admitted into the hospital to-day; under Mr. Partridge's care. At present, the integuments of the scalp, above and below the wound, are tender and swollen, extending also to the forehead, both eyelids, and cheeks. The strips of plaister were removed yesterday; the edges of the wound are in very good apposition; no union has taken place in any part of the wound; there is a copious, thin, watery discharge from it. There is so much œdema of the eyelids that she is unable to open them; pulse 100, feeble; tongue dried and furred, appetite poor; is very restless. Ordered a pint of beef-tea, pint of stout, pint of milk, and three ounces of wine.

6.—Has been very restless during the night; has taken all the diet that was ordered yesterday. The erysipelas has extended over the whole of the face, and backwards on both sides towards the ear; tongue brown and furred; there is still some discharge from the wound of the same character; has no appetite; pulse full, 100; respiration thirty in a minute. An incision three inches long was made over an œdematous portion of the scalp, corresponding to the parietal suture (sagittal), from which a good deal of serum, mixed with pus, escaped, besides a good deal of hæmorrhage. Has been a little delirious. Continue the fomentations to the head and face; also the same diet, and the ammonia.

7.—Has been very restless during last night and all this morning. The erysipelas extends from the face down the neck, in front and behind; the integuments very tense and shining; there is a good deal of swelling about the forehead, but no fluctuation anywhere to be perceived; pulse 130, more feeble; answers questions rationally, but is in a state of constant stupor (in which she mutters to herself), from which she is easily roused. Ordered two pints of stout, two of beef-tea, two of milk, and eight ounces of wine. R. Pil. coloc. co. gr. x. statim.

3 P. M.—Both the eyelids are very œdematous; the integuments of the face, neck, and scalp are tense and shining; puts her tongue out readily; when she is roused from the stupor, complains of much pain in the head; is very thirsty, and continually endeavours to get out of bed; pulse and respiration the same as at the last report. Continue the same diet and ammonia.

7 P. M.—Continues very restless, and, on account of the constant attempts to get out of bed, she was restrained; pulse and breathing the same; is busy fidgetting with her hands, as if endeavouring to catch some imaginary objects before her; bowels gently open yesterday. Continue with same diet and medicine. R. Haust. sennæ. co. ℥iss. statim.

8, 10 A. M.—Has been very restless all night, requiring permanent restraint, otherwise would have got out of bed; the erysipelas does not extend; the scalp, face, and neck are tender; there is no fluctuation to be perceived any where; there is a good deal of œdema over the whole of the scalp. She is sensible when roused from the stupor; bowels unconsciously open; still fidgets with her hands. Continues the same diet.

11 P. M.—Pulse, 120; very feeble; respiration, 48; has been very quiet since five o'clock this evening; takes her drink without any difficulty in swallowing; the erysipelas extends over the sternum; tongue very dry, brown, and furred. Increase the wine from six to sixteen ounces.

9.—Has not attempted to get out of bed during the night; passes her urine and fæces unconsciously; has not muttered much to herself since the last report. Has not been able to swallow either wine or medicine since early this morning; the breathing was accompanied with loud ronchus, which soon ceased, but the difficulty of breathing continued till her death, about eleven o'clock this morning.

Sectio Cadaveris, twelve hours after death.—Body not emaciated. The redness of the scalp, face, and neck observed during life had nearly disappeared; there was no union throughout any portion of the wound; there was a good deal of dirty-looking watery pus between the lower detached portion of the wound and the lacerated occipito-frontalis tendon; the loose cellular tissue beneath this tendonous expansion was infiltrated with pus and serum; this was not confined to the extent of the wound, but was pretty equally and universally diffused beneath the tendon; there was no pus or serum underneath the temporal fascia or muscle; but the tendinous and muscular fibres of the latter wanted their usual healthy florid colour, also those of the former their healthy glistening appearance; the pericranium was readily detached from the cranium, leaving its cutaneous surface covered here and there with patches of blood, which were easily removed; the dura mater was easily detached from the internal surface of the cranium; this membrane was also more vascular than usual; the arachnoid membrane was generally opake; beneath it and in both lateral ventricles there was altogether about two ounces of clear serum; the erysipelas had extended to the soft palate, which was somewhat œdematous, as well as the mucous membrane at the root of the epiglottis; there were no deposits of pus in any of the cutaneous veins about the head and neck, nor in any of the thoracic or abdominal viscera, all of which were healthy.

Remarks.—In this case, from the very beginning, stimulants were administered; *first*, on account of the advanced age of the patient; and *secondly*, because it is agreed upon by most practitioners of the present day that, with few exceptions, stimulants given in the commencement answer far better than beginning with depletion and ending with stimulants, the tendency of the disease being, like continued fever, to depress; the only question, perhaps, to be decided was whether or not incisions ought to have been made in the œdematous portions of the scalp; it is very probable, judging from the depression which followed the first incision, together with the loss of blood, that more harm than good would result from such a procedure; had more incisions been made, it would not have been necessary to make them through the temporal fascia.

PATHOLOGY OF EXPECTORATION.

By S. Wright, M.D., Edin., F.S.A.

Physician to the Birmingham General Dispensary, formerly Senior President of the Royal Medical and Royal Physical Societies of Edinburgh, &c. &c.

Local Symptoms and Physical Signs.—These, of course, are as numerous and as diversified as the diseases which the expectoration accompanies. The inflammatory action, of which the more viscid and transparent form of the sputum is constantly pathognomonic, may be masked in its usual physical manifestations by contingent circumstances. When otherwise, the stroke-sound of the chest, at first little deviating from what is natural, gradually becomes less sonorous, and is finally so completely dull, especially in the lower portions of the lungs, as to indicate an engorgement or obliteration of their cellules. If the inflammation be severe and extensive, a diminished motion of the ribs is generally observed in the act of respiration. This is best seen in comparing the respiratory action of the two sides of the chest when the inflammation is confined to one lung. The sound of auscultation is rough or sharp before the appearance of expectoration; this having commenced characteristically, a bubbling ronchus is heard, which at last advances to confirmed crepitation, general or partial. If the latter, the normal breath râle is heard simultaneously with that of crepitation. As the sputa become thinner, more opaque, and diffluent, the natural respiratory murmur is heard with a gradually increasing distinctness and extension, until it is found to be completely restored; as they diminish in quantity, and become purulent and fetid, or resemble prune juice, the crepitating sound grows less distinct, is heard only at the termination of an inspiratory act, or during cough, and at last ceases alto

gether. With these several indications of local disorder and mischief, are cough, pain, dyspnœa, fever, anxiety, &c., in corresponding ratio.

The physical signs which accompany the chronic expectoration of thick mucous sputum are, for the most part, confined to a sonorous or bubbling ronchus, chiefly distinguishable in the larger bronchi, with dyspnœa or irregular respiration. Sometimes, however, the rhonchus will be more mucous, or crackling, and even sibilant or blowing. Occasionally bronchophony is recognised, and also the hollow sound of pectoriloquy. These are mild or severe, according to the amount of functional or structural disturbance with which the bronchial tubes are affected. In other cases, again, the indications furnished by the lungs will be perfectly normal, and the remote cause of cough and expectoration is found in a depraved action of the stomach or liver.

Pathology.—Inflammation of the parenchyma of the lungs is the pathological condition of these organs which accompanies the expectoration of the glairy and viscid form of "thick, opaque, mucous sputum." As before said, the viscidity is a measure of the inflammatory action. When the sputum is of a rusty or orange colour, it denotes a proportionate engorgement of the vessels ramifying in the inflamed parts. The morbid appearances are, redness, deep and variously shaded, of the lungs, often traceable in the smaller bronchi; increased density of the lungs, which, however, pit on pressure, and retain some degree of crepitation. According to their state of engorgement is the facility with which they sink or float in water. The tissue, when cut into, generally exhibits some degree of sponginess, and the incised surface exudes bloody serum or spumous blood; it may also show, here and there, spots of hepatisation. Usually the substance of the organ is easily disintegrated between the fingers.

In cases of chronic expectoration of the more opaque and diffluent variety of this sputum, the pathological condition consists for the most part of local congestion (non-inflammatory), irritation, and depraved secretion. The *post mortem* appearances are, usually, hypertrophy, regular or irregular, of the bronchial lining membrane, dilatation or extension of the bronchi, pulmonary emphysema, calculi in the lungs, thickening and adhesion of the pleura, hypertrophy or aneurism of the heart or its larger vessels, &c. But as often there are no morbid appearances whatever to account for the symptoms and the secretion.

Treatment.—During the secretion of the glairy viscid or rusty sputum, antiphlogistic treatment is imperatively indicated. The character of the expectorated matter is a pretty sure guide for the amount and continuance of the reducing plan. Directly that this matter improves, the patient may be considered to be in the way of recovery. Mercurials and antimonials are of great service. I have frequently prescribed large doses of the bicarbonate of potash or soda, from one to two scruples three or four times a day, with excellent effects.

In chronic expectoration of the more opaque and diffluent sputa, quinine or muriate of iron is of most service to young or adult subjects; but old people generally derive greater benefit from small doses of opiates, and stimulating expectorants, such as squills, ammoniacum, benzoin, and senega. But the most useful remedy I have ever met with in such cases is the balsam of copaiba. In doses of twenty drops twice or thrice a day it is often of magical service in relieving the dyspnœa and allaying the cough and expectoration.

Muco-albuminous Sputum.—This is a sputum much oftener mentioned than met with. The vague style of expression, and the abuse of technical terms, which distinguish and disgrace the majority of writers on medicine, are found never more abundantly than in a description of the contents of a spitting vessel. A man will coolly pronounce the sputa to be purulent, or muco-purulent, without giving himself a moment's trouble to discover the actual presence of pus. Dirty discoloration will satisfy one investigator that the secretion is purulent; a mere fœtid odour will convince another, and a third will quietly content himself that the matter is pus if it only looks yellow and flows rather easily. So, on the other hand, a mere flakiness, opacity, viscidity, or density of sputum, will suggest to one wise head to call it *glutinous*, and to another to describe it as albuminous. It would be interesting enough could we be told how many have busied themselves to determine the existence of albumen in sputum, out of the vast number who have boldly talked about it. The sputum is by no means uncommon, but, as we have said, the frequency of its occurrence bears no comparison with the frequency of its description.

Appearance and Qualities.—Muco-albuminous sputum is generally met with of about the density and consistence of ordinary nasal mucus. It is sometimes nearly transparent, like the white of egg, but oftener opaque or pearly looking. It is more rarely found tinged of a blue, green, yellow, or tawny hue It is constantly alkaline from the presence of soda, but it is very variable in its proportion of saline constituents, which are chiefly nitrate of soda and phosphate of lime.[1] It is usually frothy throughout, and becomes semi-liquid by rest and exposure. In plethoric and vigorous subjects it is frothy on its surface; less often it is discharged mostly expectorated alone, in masses or pellets which are with difficulty dislodged, globular or flattened, and of about the circumference of a sixpence or a shilling. In less sanguineous subjects, and in such as are diseased or debilitated, it is generally accompanied with a thinner mucous or muco-albuminous fluid, in which it floats distinctly, or with which it is somewhat minutely intermixed. It is tasteless, and possesses little or no odour.

We must not, however, decide that the sputum is albuminous until we have proved that albumen actually exists in it. For this purpose, it is best to take any convenient quantity of the matter, and dilute it with ten times its own volume of distilled water. The mixture should be occasionally agitated for the space of five or six hours.[2] It may then be passed through very porous paper, or through one or two folds of muslin. The filtered liquid must next be acidulated with nitric acid, the most available proportion of which is, one drop to every drachm of the sputum. The mixture, after a little further agitation and rest, may then be heated to the boiling point. If any albumen be present, it will be indicated by coagulation or flakiness. Another portion of the filtered liquid, without being acidified, may be treated by galvanism. If there be albumen, this will form a coagulum round the positive wire, and free soda will collect upon the negatives.

Pathognomonic relations. This form of sputum is sometimes met with in simple bronchitis. Suddenly, and without any obvious cause, the respiration will become partially stridulous, the cough aggravated in frequency and intensity, and the sputa will immediately become opaque and pearly-looking, with no decrease of viscidity; or retaining their original transparency, will yet indicate, on the application of tests, the presence of albumen. This deviation from common circumstances is chiefly observable in the bronchitis of young subjects, when the affection seems to be intermediate between simple inflammation and genuine croup. It differs, however, from the latter, in that the effused matter never acquires the firm and definite consistence of false membrane, but almost as soon as discharged from its vessels is expectorated, either transparent or opaque. In adult subjects it is less frequently met with, and least of all in the bronchitis of advanced life; in the bronchial accumulations of suffocative and suddenly fatal bronchitis, this variety of sputum has a chief share. In severe cases of pneumonia it is apt to occur, and if the patient be not at the same time relieved by a copious and free expectoration of the albuminous fluid, its accumulation is liable and likely to impede the function of the lungs, and to cause death by apoplexy or asphyxia. In croupy subjects it sometimes attends the cough of an ordinary cold, and, indeed, not unfrequently appears to serve as a substitute for a genuine attack of croup. In any sudden aggravation of existing irritation, or inflammatory action of the lungs, this sputum may be looked for, and its presence is always indicative of an accession of mischief. Any source of irritation directly affecting the lungs or bronchi, may also give rise to it; I have met with it in dry grinders, especially grinders of needles, and in workmen exposed to the fumes of sulphur, metals, acids, and noxious irritating gases.[3] In such subjects it often exists consentaneously with the deposit of tubercular matter in the lungs; it has been observed in inferior animals, collected in the trachea and bronchi. Youatt, Valentine, Rush, Duprez, and others, have found in dogs and horses; Ghisi and Gohier, in cows; Double and others, in lambs and cats. In birds, and especially in chickens, it is met with in the disease called "pip," when this is not sufficiently severe to run on to the formation of a distinct membrane in the air passages.

"Muco-albuminous sputum" sometimes occurs in common influenza and catarrh, and without any obvious change or aggravation of the general or local symptoms. In such cases, the proportion of albumen to that of mucus is generally very small. In the severer forms of scarlatina this sputum is observed. I once had a case in which the expectoration was critical; it manifested itself suddenly and profusely, and continued long after the abatement of the inflammatory symptoms. Here the flux seemed to be analagous to the albuminous excretion, which, under similar circumstances, often occurs from the kidneys.

Local Symptoms and Physical Signs.—When "muco-albuminous sputum" is discharged profusely, when the ratio of the albuminous constituents to the mass of sputum is not considerable, and when no active inflammatory symptoms, either local or general, accompany the expectorations, the sound of the chest, both by auscultation and percussion, are often, in no sensible degree, at variance with what are natural. Nor are there any indications, in many such examples, to denote a deviation from a normal state of health and strength. When, however, the secretion of this sputum arises from local disease or disorder, when the sputum is not considerable in quantity, is with difficulty expelled, and is abundant in albumen, the local signs, as elicited by physical diagnosis, are generally very clear and conclusive. They usually consist, at the commencement of the expectoration, of a mucous râle, chiefly in the superior and middle portions of the lungs. At such time the stroke sound of the chest is perfectly natural. At an approaching period, which varies from a few hours to as many days, percussion elicits a dull sound in the lower half or third of each lung. A bronchial murmur then becomes manifest, and in severe cases will increase to perfect bronchophony. In instances, however, of muco-albuminous expectoration, I have never met with bronchophony, unless the sputum contained at least one half of its volume of albumen. This fact would appear to be curious, inasmuch as bronchophony, under other inflammatory and congestive conditions of the lungs, often prevails, and yet the sputa are entirely free from albumen. It shows, however, that the form of pectoral inflammation which albuminous sputum accompanies, is capable of being measured both in its intensity and its progress by the albuminous condition of the expectoration. As the inflammation subsides the amount of albumen lessens, and the sputum becomes thinner and usually saline. It generally passes into the "thin" or "thick mucous" variety, and in rarer instances into the "purulent." It scarcely needs to be remarked, that the inflammation which gives rise to albuminous expectoration is also productive of the other more common symptoms of pneumonia or bronchitis.

Pathology.—The secretions of "muco-albuminous sputum," depend upon either general or local vital conditions. When occurring in its simplest form, profusely, and in young or adult subjects, and without the evidence of any specific morbid

[1] This matter sometimes lodges in the trachea, or bronchi, and collects almost like the false membrane of croup. In this state, Schwilgue found it to consist of albumen, with a small quantity of carbonate of soda and sulphate of lime.

[2] Less time will suffice if the sputum be of the transparent variety.

[3] Albers, Duval, Jurine, and Schmidt, produced it artificially in inferior animals, by compelling them to breathe the fumes of sulphuric or muriatic acid, and by injecting into the trachea bichloride, or peroxide of mercury dissolved in turpentine, tincture of iodine, solutions of nitrate of silver, &c. The animals experimented upon were wolves, sheep, cats, dogs, and fowls.

actions, it appears to be referable to an unusual albuminous condition of the blood, or to a want of the vital property, or of the sensibility to vital stimulus, which are necessary to a higher development and organisation of the albumen. This deviation from a healthy state is probably owing to an action, *per se* [4] of the blood, aided by some derangement of the nervous system. The albumen of the blood, as the least vitalised animal constituent of it, is the first to suffer from any shock, whether spontaneously of the blood, or communicated through nervous influence to it, and becoming more or less devitalised, is with proportionate facility discharged by some secernent or emunctory organs.

In different subjects, and in different conditions of the same subject, inflammation of mucous surfaces, especially pulmonary, is attended with very various local results. There may be simply an increased quantity of the natural secretion of the part, or this secretion without undergoing any specific change may be variously modified, pus may be produced, or a false membrane, or there may be a muco-albuminous exudation. These different consequences of inflammation are in no wise dependent upon the intensity of it; but appear to be owing to a modification which the inflammatory action receives from local or general sources. The bronchitis of some subjects is invariably attended with albuminous expectoration, of others with a purulent discharge, whilst in a third its symptoms and secretion will resemble those of croup. So also will artificial irritation of the trachea or bronchi produce equally variable results. We know that youth and a sanguineo-phlegmatic temperament are favourable to "muco-albuminous" excretions, that solid albuminous or fibrous exudations are chiefly met with in the inflammation of plethoric and vigorous subjects, and that purulent discharges from mucous membranes are generally limited to the cachectic and debilitated. But pathology will aid us no further in solving the ultimate question. We must be satisfied with the facts as we find them, and with only an approach to their explanation.

The post-mortem appearances after fatal inflammation attended by "muco-albuminous" expectoration, are thickening and vascularity, uniform or in patches, of the lining membrane of the trachea and bronchi; the latter are somteimes constricted. The membrane now softer, and again firmer, than usual, is never found ulcerated The marks of inflammation are generally confined to the lower part of the trachea and the commencing bronchi—they less frequently extend to the terminal bronchial branches—and very rarely reach as high as the larynx. The "muco-albuminous" exudation is usually abundant in the trachea and larger bronchi." In the smaller tubes a thinner fluid is found, but still albuminous, and I have seen it extending throughout almost the entire mass of pulmonary structures. The lungs are generally somewhat crepitant in their superior portions, but they exude, when cut into, a spumous, often sanguinolent fluid. Their lower parts are chiefly impervious to air and of a deep claret colour. They cut like liver, and represent either complete engorgement and obliteration of the pulmonary cells, or confirmed hepatisation.

Treatment.—When the secretion of "muco-albuminous sputum" is unattended with inflammatory symptoms, or with any indications of local disease, it is best that it should be treated upon a tonic plan. Cold bathing, or sponging the body on rising in a morning with cold water, is of excellent service. The preparations of iron do much good, as does also quinine with an excess of sulphuric acid. Warm aperients should be given, and free exercise, with good living enjoined. Under this treatment the sputum will soon begin to diminish in quantity, and the mucous membrane will secrete proper fluid. If the discharge be excessive, it sometimes is, catechu or kino may be added to the quinine mixture, and the throat, down to the chest, may be rubbed with croton oil, or painted with tincture of iodine.

When the sputum is dependant upon inflammatory conditions, it is of course requisite that depletive measures should be used to whatever extent they may be indicated. A very good guide will be found in the tenacity of, and the amount of albumen in, the sputum. Bronchitis, which is attended with this form of expectoration, has a much greater tendency than ordinary bronchitis to become suddenly fatal, or to pass rapidly into pneumonia, and this disease has also the same great tendency to pass on to hepatisation and gangrene, rather than to be resolved, for which reasons, therefore, it is important that the indications furnished by this sputum should awaken us to every vigliance in the treatment of the diseases which it accompanies. Additionally, to bleeding, mercury and antimonials must be chiefly relied upon. Large and frequent doses of alkalies are generally beneficial.

[4] Medicines which deteriorate the blood, or diminish the energy of the nervous system, have a remarkable tendency to impregnate the secretions with albumen. Thus, in mercurial salivation, the saliva invariably has its albumen increased, and often to as much as ten times its natural quantity. The urine is also frequently albuminous, and almost constantly when the salivation has been produced by the bichloride of mercury, which more than any other preparation of this metal debilitates the nervous system. And in such cases again, we find that the blood has lost much of its vital property, and especially the power of coagulating firmly. I once injected a grain of corrosive sublimate, dissolved in an ounce of water, into the jugular vein of a healthy dog. No obviour irritation or spasm was produced, nothing but slowly increasing prostration of vital power, which terminated in death in six hours. The animal passed a great quantity of urine, which became albuminous twenty minutes after the injection, and never regained its normal character. The kidney were not in the slightest degree inflamed. In injecting sedatives, such as digitalis, prussic acid, and very dilute solutions of ergot of rye, into the veins of dogs, I have repeatedly obtained the same results. And in slow poisoning by these substances, the urine has generally been albuminous, or the bowels have from time to time discharged a serous fluid. The blood, I scarcely need say, has also been remarkably impoverished.

NOTICES TO CORRESPONDENTS.

An Old Practitioner.—*Only five or six of Dr. Williams' lectures, on the Practice of Medicine, remain for insertion. We have before stated that they were taken by an eminent short-hand writer, and have been very carefully revised by a medical man, previous to their publication.*

A Friend.—*Many thanks for the subscription; £180 were, this week, paid into court, as the damages and costs incurred by the recent action against this Journal.*

Mr. Pearse.—*We have given strict injunctions concerning* Mr. Pearse's *Journal.*

Dr. Lewins *wishes us to correct a statement, which appeared in his communication on uterine and ovarian diseases, to the effect that, the late Dr. Mackintosh was the first to question the accuracy of the generally-received opinion respecting hour-glass contraction of the uterus. Dr. Lewins informs us that he is convinced, the merit of first describing the actual condition of the organ, in the state referred to, is due to Dr. John E. Douglas, of Rutland-square, Dublin.*

Electron.—*We know of no better caustic for the formation of issues, than the potassa fusa. The depth of the eschar would, of course, depend on the mode of its application. We suspect our correspondent not to be a medical man, and, if so, we recommend him not to meddle with matters of this nature. Electro-magnetic apparatus are frequently advertised in the* Medical Times.

Noel.—*We should not ourselves exceed four or five grains of the remedy daily. It has been stated to possess an effect on another secretion, which, possibly, our correspondent's patient might not wish.*

A Constant Reader *notices an advertisement, which appeared in our last number, for an assistant, to take charge of a nervous invalid. The duties are said "to be light; and he will be treated as a gentleman"—he is, nevertheless, required to "shave" and "dress" the patient, to "wash and ride out with him," &c. Our correspondent suggests that it is a pity the profession of "barber-surgeon" was ever abolished.*

Lucius, *the author of a clever pamphlet, lately published, reminds us that Mr. Wakley transferred an elaborate lucubration of the* 'Times,' *into his* 'Lancet,' *in August last, as the leading article of a hebdomadal number of that scurrilous publication." —He continues "Allow me, Sir, to advise you, for, once in your editorial life, to follow the example of the extraordinary* conducteur *of that periodical, and, with all convenient speed, to copy, as much of the leading article of last Saturday's* 'Standard,' *into the columns of the* 'Medical Times,' *as you deem expedient.—The article to which I direct your attention deserves to be recorded where it will be more permanently useful, than it can be in the pages of a daily newspaper—and it is as à propos to* your *late position—and to that of a notorious personage, as if it had been written for your special benefit.—In the words of the immortal Burns, with you and the* 'Standard,' *I exclaim—*

'Here's freedom to him that would read,
And freedom to him that would write:
There's n'ane ever feared that the truth should be heard,
But they whom the truth should indict.'

[*We, last week, published the leader referred to.*]

F. S. A.—*The prescription referred to is only fitted for a peculiar form of the malady, and is not without danger. The local ailment, in ninety-nine cases out of a hundred, is not the malady, but its symptom; wherefore, local applications might, probably, be worse than useless—mischeivous.*

A strong appeal has been sent to us on behalf of the 'Dublin Statesman and Warder,' *which has lately been mulcted in the sum of* 500*l, for discussing the abuses which were said, generally, to exist in Irish factories. A clergyman swore that the article had a particular reference to a factory about which the editor of the Journal knew nothing; whereon a jury under the judge's encouraging direction gave damages* 500*l.*! *The appeal certainly deserves to be heartily responded to.*

Curioso.—*We regret we are unable to answer our correspondent's question. We have enquired of several publishers, and can get no information of any work having been published on the subject. The committee do not restrict the subscriptions solely to the profession.*

Ornopinein.—*We regret we cannot supply our correspondent with the information he requires.*

A pupil *writes as follows*:—

"Irregularity of attendance on the part of some of the surgeons at the Jervis-street Hospital, Dublin. —The absence of a local medical press, at all calculated to represent the interests of any branch of the profession; together with the fact of the *Medical Times*, from its extended circulation, and well-known ability, being now justly considered the only efficient organ through which the sense of the profession can be brought to bear on those abuses, which, occasionally, 'like clouds upon the atmosphere,' obscure its nobler attributes, must plead my excuse for thus trespassing on your valuable span, while I expose the 'foul play' practised on he pupils of the above hospital, by those to whose charge their instruction is entrusted." *This is, of course, the prelude to a virulent attack on some of the officers of the institution referred to. We feel assured that, should any slight irregularity exist, this notice will be sufficient to ensure its correction. At all events, we can take no further notice of the matter unless the communications be duly authenticated with the writer's name and abode.*

Enquirer.—*The first four volumes of the* 'Medical Times' *were published under an entirely different proprietorship and management. We wish our readers, generally, to remember this fact.*

A Constant Reader, Dublin.—*Dr. Graves' admirable lectures were revised by the author. We wish we could see some such lectures delivered on this side of the water. The* 'Medical Times' *is, we believe, the only periodical in London, composed entirely of original matter.*

Will Q. E. D. *demonstrate his name to us confidentially?*

Dr. T., Wilts.—*We shall aim to set the matter right of which he speaks.*

A Friend.—*There were* two *meetings held. The second is the one referred to.*

W. H's paper is inadmissible, for reasons which he will, at once, appreciate. The surgical operator named is mentioned under a false aspect; and the letter itself is unauthenticated.

S.—*The humorous "analysis" of the singular medico-legal points has been received; but a rumoured change makes its publication undesirable. We shall preserve the M.S. for S. Would S., in the event of our having to use the paper, allow us the privilege of a few touches under our own hand?*

A Medical Pupil, *by remitting the guinea, will be enrolled as an annual subscriber.*

We think it advisable not to insert the letter of "Q," animadverting on Mr. Bottomley's lending himself as an "humble instrument" to some very equivocal games of professional cross-purposes, and demanding why the names of no Committee could be mustered, or consequently could be published, and containing sundry other criticisms of perhaps unneeded severity. We dare say Mr. Bottomley, till entrapped into co-partnership, had a very imperfect notion of the small capital, save of false pretences, on which his political coadjutors rested to keep up their small agitating business.

A Handsome Portfolio *for holding the* "Medical Times,"—*very desirable to those who would keep the numbers clean for binding, and easy of reference—may be had, by order of any bookseller, or at the Office, price 5s.—An allowance is made to the trade.*

Dr. Jacob's *letter will be noticed next week.*

THE MEDICAL TIMES.

Saturday, July 19th, 1843.

And thus the native hue of resolution
Is sicklied o'er with a pale cast of thought;
And enterprises of great pith and moment
With this regard their currents turn awry,
And lose the name of action.—Hamlet.

The order paper of the House of Commons has every evening for the last ten days been graced with "The Physic and Surgery Bill" as a measure for each day's discussion. By some mystery we cannot penetrate, but which the Scotch Colleges can perhaps explain, Parliament has been very busy and active, and the Bill is still among the things "to *be*" discussed. Of course every day's delay lessens proportionably the chances of the issue we wish; and if last week we had no *hopes* of such a result, this week we have the feeling that there is no *chance*. The probability is that Sir James Graham will formally introduce his bill to the House before the close of the session, making a detailed statement of the alterations he proposes, and, getting the Bill printed, leave it for the Profession's consideration to the beginning of the next session.

How, then, stands the question of Medical Reform? The delay being given, is the necessity for amelioration less? The demand weakened? The chance of concession less considerable? We surmise not.

The intrigues, the threats, the opposition of the corporations may put off the evil day—they cannot avert it. The strength of feeling for improvement that now pervades the profession is at once unparalleled and resistless. The cause of Medical Reform, instead of being the stock in trade which furnished a few characterless scoundrels an equivocal notoriety and precarious subsistence, has become an integral portion of social philosophy, and nineteen-twentieths of the best medical men in the empire are now ready to do their best to achieve the organisation which they are convinced medical polity requires. It is no longer a small clique of discontented spirits, plotting in obscurity and suffering in some low pandemonium, their own uprise and others fall. Public ends are now sought with public and disinterested views, and the Medical Reform party includes at length what three years ago we insisted it should include, all that is respectable, all that is classical, all that is worthy, and all that is philosophical in the profession. Out of official circles there is *now* scarcely a *thinking* practitioner of respectability who is not earnestly joining in the demand for improved Institutions! What a happy and almost unhoped-for change in medical relations! With how much gratified conscientiousness do we look back on the humble but reiterated labours which we, in an earnest spirit, have contributed towards providing that result! Medical Reform, like the *Medical Times* itself, was when we found it, in the kennel. It has been cleansed, and the higher, better, and more ennobling qualities of its nature being fully displayed, it is now the adopted of all!

With this universal *call*, or rather *struggle*, for improvement, how short-sighted is the comfort of those who are singing Hosannahs because the bill *may*, after all, be postponed. So universal and so urgent a demand for change presupposes no trifling cause; and when, with this consideration, a further thought is given to the actual character of the government of the different Medical Colleges in the kingdom, and the unsatisfactory position occupied by a class forming nine-tenths of its Doctors (the General Practitioners), the conviction is instantaneous that the hand of Death is impressed on the whole surface of our present polity, that a thorough change in the Profession is inevitable, and that the longer the delay that is interposed the more complete the change when it comes! On the whole, then, the non-success of the Minister's bill infers no failure of the cause of good Medical Government. The presumption is rather the other way. The forces for improvement are hourly increasing, and the partial boons which will content this year, will be felt by all to be inadequate the next.

The great duty, meanwhile, of the Profession and those acting for it, is to conciliate the support of those who yet abstain from joining in the movement. The enlightened Physician, or accomplished pure Surgeon not included in the pale of official contamination, have as deep an interest in the re-organisation which will give British medicine the stimulus that has so long been wanting, and which the active character of the age requires, as any portion of the class of General Practitioners. The present system is most unfavorable to merit for the *consulting* doctor. Success in his profession, and access to the high places of government, is the reward of but *one* worth, when two should be indispensable—the reward not of *scientific*, but *social* excellence. It is not the retired thinker, but the convivial conversationalist—not the child of science, but the son of fortune, that rules an intellectual Profession! Wrong—mischievously wrong—is this. It is so felt, and nothing is required to secure the cordial cooperation of *all* to a remedy, but a maintenance of a conciliatory and kindly bearing between us and those gentlemen who yet hold aloof from us. Important, and pregnant with good results, is this consideration if it lead to the abandonment of those terms of reproach—"Dubs," &c., bandied by one class against another, and which, by an incomprehensible excess of folly, keep in opposition and hostility men who have a common interest in cordial union.

But the great practical object the General Practitioner must keep steadily in view above all others is to maintain, if possible, in increased efficiency and power, that National Association which has sprung up to our hand, in magical potency, at the very instant we most wanted it. The Association is a gigantic instrument suited to the gigantic nature of the work that is to be done. It holds in its hands at this instant the future re-organisation of the Profession. Evidently there is about it a wise, a cautious, and enlightened management. The wonderful union, combined with no want of decision, which has hitherto characterised it, offers us a consolatory and cheering pledge for the future. So long as its counsels are thus directed, so long will the Profession, in augmenting numbers, cluster about it for its support. We are above all things anxious for this permanency of organized power, for it includes in it every element of our hope. With it we are not only irresistible for defence of what is right, but certain of ultimate success in the attack on what is wrong. We act on Government immediately as a high negociating power with fixed opinions and formidable influence; and Parliament, wishing to do what is right and acceptable, will have an authoritative voice to encourage them in judicious legislation. Even State Ministers might be taught to feel that a Government, if resisting our demand when placed before the House by one of its most distinguished members, would be perilling its own permanency; and beyond a doubt, a change of ministry, arising from whatever cause, would be the triumph of our principles, and the reward of our united perseverence. But should even Parliament and Government alike withhold consent, our success might be not one whit the less complete if, resolute against corporate impolicy, we hold tenaciously and enthusiastically together. A single day could turn the National Association into "A Voluntary Incorporation," "A College of Physicians and Surgeons of Great Britain and Ireland," with a well-paid Court of Examiners, consisting of the first Physicians and Surgeons of Europe, a Medical University, with some of Europe's first Professors, and a Museum devoted to the whole range of Medicine, and appealing to Professional support by every claim that can excite to enthusiasm, or warm to generosity.

We believe the Committee who have the honour of standing at the head of so large a portion of their professional brethren are fully alive to the fact that the Association, *as an Association*, is yet capable of immensely augmented development. There are thousands of Surgeons and Physicians (for this is, after all, the true classification of the Medical Profession) in lee-

land, Scotland, and in England, who are yet to be enrolled; there are hundreds of districts which have yet not their local secretary; there are arrangements yet to be made which will bring the Committee's operations to the door of Colonial support and sympathy; and we have no doubt that the breathing time between this and the next session will be vigilantly employed, in effecting these, and the other measures which may make the Association all it is capable of, and fit it forthwith to enter that new sphere of glorious and not less *useful* existence which is lying temptingly open to them. But we must return to this again.

REVIEWS.

Pulmonary Consumption successfully Treated with Naphtha; 2nd Edition. By John Hastings, M.D., Senior Physician to the Blenheim Street Dispensary. John Churchill.

We noticed this work on the appearance of its first edition. The successful cases then narrated by Dr. Hastings are spoken of now as still successful, and the confidence of the author in his new remedy seems unabated. The public adhesion to the new faith of Dr. Hocken, of London, and Mr. Donovan, the eminent chemist and apothecary of Dublin, is certainly presumptive evidence in its favour; and the too general hopelessness of the malady Dr. H. takes under his protection, asks from us, in reference to his views, the exercise of a very tolerant censorship. The present edition contains an appendix, with some useful statements on the propriety of perforating tuberculous cavities in the lungs, supported by a couple of original cases communicated to the author by Sir Henry Marsh.

Apology for the Nerves, or their Influence and Importance in Health and Disease. By Sir George Lefevre, M.D., &c. London: Longman, Brown, Green, and Longmans.

A very vague title to a very vague book, which is, after all, sadly miscalled. To prove the influence and importance of the nerves in *disease* and health is scarcely to apologise for them, supposing even they had need (as they have not) of an *amende honorable* from a West-end physician. Sir George can do more, we suspect, than his present book clearly implies. We have guesses and rude conceptions on subjects where a little study would have given clear and precise opinions, and a *trifling* work, *de omnibus rebus et quibusdam aliis* (not one of the many topics, however, thoroughly exhausted), when, with forethought and some little planning, we might have had a systematic and useful treatise. Our author seems terribly desultory in his studies, and will not apparently be less so in his writings. Of course, with a clever head full of odds and ends, picked from all quarters, travelled and untravelled, we cannot have a very dull book, and therefore the "Apology," though prepared apparently by order at a three days' notice, has some interesting gossipping pages, which *may* repay a *very* hasty and superficial reading. When Sir George will write the book he *can* and *should* write, we will give him a more extended notice; in the meantime, if he take our hint, he may register us in his books as not the more plain-spoken *only*, but most *useful* of his friendly critics. We are sure we shall do him good service.

The Transactions of the Provincial Medical and Surgical Association, Vol. XIII. London and Worcester, 1845.

This is undoubtedly the most valuable work we have received from this large and meritorious Association. The Retrospective Address of Dr. Cowan is a masterly composition, in which the difficulty is to choose which to admire the most—its scientific acumen or literary excellence. Papers are also contributed by Dr. Budd, of Bristol; Dr. Hocken (the misused of Dr. Forbes); Mr. Giles, of Stourbridge, and a distinguished contributor of our own; Mr. Crosse, the surgeon of Norwich. Mr. C.'s paper is a very elaborate one on "Inversio Uteri," and is well worthy his eminent surgical repute. Will Drs. Hastings and Streeter, and the Council of the Association, allow us to suggest to them that a second volume of Transactions annually would be a boon to the profession, and a very useful mode of employing the funds of the Association?

BOOKS RECEIVED.

Elements of Phrenology. By George Combe. Sixth Edition. Edinburgh: Maclachlan, Stewart, and Co.

No man since Gall has done more for phrenology than George Combe. With all the enthusiasm of an apostle, he has all the temperance of a philosopher. It is needless to say (the *sixth* edition before our eyes) that the "Elements" are the text-book on the "science," and that eminently do the *animus*, intelligence, and literary craft of the author merit for them the distinction.

Lectures on the Theory and Practice of Surgery. By the late Abraham Colles, M.D. Edited by S. M'Coy, Esq., F.R.C.S.I. Dublin: S. J. Machen, Westmoreland Street.

There is very little of "Theory" about this course. Dr. Colles was all practical; and Mr. M'Coy appears to have done this characteristic of his lectures full justice. As a record of the Professor's experienced opinions on surgical practice this work is valuable. We can say little for it considered as a complete work on surgery in the year 1845.

The Stutterer's Friend, &c. By J. Wright, Esq. Second Edition.

This is a "plea" by the author in answer to two "inhuman" works—the one by Mr. Yearsley, recommending the snipping of the uvula; the other by an author who writes incog. under the name of "Physician." Mr. Wright claims to have "humanity and common sense" on his side; but whether that be the case, or whether, if he be right, his opponents have something better on theirs, we are unable to determine. The interested *savan* will perhaps consult the pamphlet for himself.

History of the York Dispensary; containing an account of its Origin and Progress to the Present Time, comprising a period of Fifty-seven Years. By Oswald Allen.

The author, a patriarchal surgeon, in a very pleasing spirit, devotes 116 pages to the record of what, in a local sense, are the important *res gestæ* which have made the York Dispensary *all* it is.

A Collection of Cases of Apoplexy, with an Explanatory Introduction. By Edward Copeman, Surgeon.

Mr. Copeman has collected from his own practice, and the records of the practice of others, published in the journals, 250 cases of apoplexy, with the view of shewing that bleeding in affections of the brain is less justifiable than is generally surmised. As far as he goes, Mr. C. deserves all our commendation; the matter of regret is that his facilities as a statistician have been so small.

Report of the Parliamentary Committee of the Loyal National Repeal Association on the Bill for Regulating the Profession of Physic and Surgery, with Observations on Medical Education. Dublin, 1845.

Dr. Gray, the author of this very luminous and able report, deserves the thanks of all members of the Profession, of both sides in politics, for directing the attention of the powerful Association of which he is one of the leaders, to the question of medical reform. Dr. Gray stands up manfully for the apothecaries of Ireland, but most distinguishes himself for the lucidity and power with which he establishes the necessity for a *practical* examination. The Committee of the National Association will read this report with advantage.

The Meteor. Nos. 1 and 2. Edited by John Leslie Buckstone. London: Westerton.

A new periodical by one equally well known for his affluence of humour, as actor and author.

The National Temperance Magazine (June). Leicester.

This number contains, with the usual matter, a sprightly, but certainly not brief, attack by Mr. Morris, the surgeon of Spalding, on the principles of Teetotalism. Dr. Grindrod and that gentleman are in hot warfare on the subject, much less, we fear, to its elucidation, than to the amusement of those interested in it. We can easily understand that Mr. Morris, living in a fen district, has a horror of water, but to us living in a London neighbourhood, our eyes wounded hourly with the sight of Gin's hideous trophies of pallid faces and ragged clothes, the more natural matter of aversion is alcohol. If Mr. Morris would take our advice, he would offer no let to the worst principles of logic (of *other* people) that reclaimed a drunkard. With an English audience, two words for alcohol by a "doctor," is at least one for intoxication. There is no great fear of the virtues of gin being *underrated*.

Cosmos; a Survey of the General Physical History of the Universe. By Alexander Von Humboldt. No. 1. London: Baillière.

This is *the* "Vestiges of Creation." The subject—the grandest of all human themes—belongs of right to Humboldt—the poet-philosopher. We shall give the work the ample notice it deserves when a little further advanced.

CLINICAL NOTES.

(No. 1.)

By Richard de Gumbleton Daunt, Esq., M.D., (Edin.,) Member of the Faculty of Physicians of Rio de Janeiro, and Member of, and late Honorary Secretary to, the "Parisian Medical Society."

(For the "Medical Times.")

In the occasional papers of which this is the first, it is my intention to consign such facts and observations in morbid physiology and therapeutics, on the influences of various nationality, hygienic conditions, &c., as expressed in the phenomena of disease, as may appear to me illustrative of views or states not embraced in the writings of the routine nosographists; and as they are drawn from a tropical clientelle, the subject of the climate and diseases of the tropics will come more or less prominently forward.

One of the earliest cases of interest presented to me in Brazil, was a case of epilepsy. In the close of 1843, I was called to see a surgeon, native of one of the Azores, but long resident in a town on the sea coast, a few miles to the south of Rio de Janeiro, whom I found in the following state:—He was a robust man, of 36 years of age, but rapidly wasting; his nervous system so shattered, that the greater part of each day was spent in tears. He was then suffering from one, two, and even three violent attacks of epileptic convulsions daily—more frequently occurring during the night than in the day. The lacerated state of the tongue evidenced their violence; the nights were passed without sleep, which severe ostalgia of the frontal bones prevented; appetite was gone; defæcation was difficult; micturition frequent; vision and olfaction impaired, and the os frontis appeared irregularly thickened. The skin was dry and harsh, with scattered cupreous maculæ. The patient had led an extravagant life while a student in Rio, at which epoch he had contracted several attacks of syphilis, for which he had undergone no regular treatment. Since commencing practice he had gone through much severe country labour, but had enjoyed good health up to two years and a-half prior to the period of his consulting me; from that date he had experienced pains of the bones, with frequent cutaneous eruptions, but had never had the throat affected, and his general health began to decline. He then became alarmed, and by the advice of several Rio practitioners, took various courses of mercury and diet-drinks, but without favourable results, until three months prior to my commencing to treat him, he was, after a ride into the country during the heat of the day, seized with an epileptic paroxysm. For the first attacks he was treated antiphlogistically, and with temporary relief, but the disease continued to gain ground. When I examined him, I became convinced that a perversion of the nutritive action was progressing within the calvarium, the consequence of the syphilitic poison, and urged the adoption of a therapeia based on this principle. He consented, and I prescribed as follows, depletion having some weeks previously moderated the irregular distribution of blood, which at first was very marked:—

℞ Extracti aloes ʒj., Scammonii ʒss., Olei tiglii m. ij. M. ope liquoris potassæ ut ft. massa in pil. æq. xvii. distrib. cuj. capt. æger ij. vel iij. p. r. n.

℞. Extracti lactucæ gr. vi. vel x. Omni nocte ex mistura amygdalarum.

℞. Potassii iodidi gr. v., Infusi quassiæ ℥j. M. ft. haust. quotidie sumendus.

℞. Infusi sarsaparillæ ex aqua calcis frigida ℥ xij. Omni die in haustibus ij. sumend.

When suffering from excessive pain, a few drops of laudanum were given, and a warm bath was used

thrice weekly; also counter-irritation to the nape of the neck with the ointment of the potassio-tartrate of antimony. The diet was regulated, and every means taken to dispel the melancholy which was overpowering a naturally active and thoughtless mind. In about five weeks he took a dislike to the infusion of sarza in lime-water, and infusum valerianæ ℥ xij. daily was substituted. In a fortnight from the day of his commencing this treatment a marked change was visible; the general health was decidedly better: the severe cephalalgia almost gone; the epileptic paroxysms recurring only thrice weekly, and less violent; the nights more tranquil, and all the other symptoms lessened. This amelioration encouraged me to persevere, and to resist any recourse to the ordinary formulæ in this disease, and at the end of the sixth week the paroxysms and the frontal pains had disappeared.

On the eighth week, a moral cause occasioned another, and the last fit; I induced him with difficulty to continue six weeks longer in the use of the iodide of potassium, when he at length finally discontinued it, and although for a little while longer he took some vegetable tonics, he was at this time restored to his former health, and active life—the thickening of the frontal bone, and all other vestiges of disease having entirely vanished. I ought to state that the purgative pills prescribed were given merely to the degree required for producing natural defæcation—active catharsis being in the then adynamic state of his nervous system, strongly contra-indicated.

This case while it examples an infrequent form of epilepsy, will, I trust, serve to enforce the necessity of a minute study of phenomena of each particular case of this disease, and the duty of avoiding a routine practice in its cure. As the patient in this case was ignorant of the iodide of potassium, and prejudiced in favour of mercury, my expressed views of the nature of his disease rendered him anxious to mercurialize himself again, and I had considerable difficulty in inducing him to abandon a design likely to be most fatal if practised; perhaps I should not have been able to prevent him from acting as he wished had not the plan I pursued so soon justified itself by an evident and increasing amelioration in all his symptoms. From the state of prostration of his mental faculties, and loss of tone of the nervous system in which I found him, I am convinced that under any other treatment dementia would not have been tardy in appearing.

Campinas, Province of San Paulo,
Brazil, April, 1845.

PROGRESS OF ENGLISH, ITALIAN, AND AMERICAN MEDICAL SCIENCE.

Extirpation of a Fibrous Tumour from the Peritoneal Surface of the Uterus.—Dr. Atlee has published in the *American Journal of Medical Science*, the details of a highly interesting case in which he successfully extirpated a fibrous tumour from the peritoneal surface of the uterus by the large peritoneal section. The patient was twenty-four years of age, and the disease had existed rather more than a twelvemonth. It appears to have been caused by a fall from a horse. When first seen and examined by Dr. Atlee, he found a tumour occupying the hypogastric and right iliac regions, resting closely upon the pubic bones, being prominent above the symphysis, and gradually retreating toward the spine as the hand ascended towards the umbilicus—the fundus of the tumour occupying a point one inch below the navel. The tumour was hard, resisting, somewhat uneven, and presented an edge in the right iliac region. The only tender spot on handling was on its upper surface. It was movable, and could be rocked upon the brim of the pelvis over to the left iliac region. On examining per vaginam, the finger, as soon as it entered, came against the convex surface of a hard tumour immediately behind and below the arch of the pubis, and resting firmly against it. This rounded surface extended throughout the pelvis, pressing the uterus down against the perineum and rectum so firmly, that it required some slight force to insinuate the finger between them. Upon the inferior face of this tumour was a ridge about the thickness of a finger, occupying a central position, and running in the antero-posterior direction, which, evidently, was the cervix uteri, the os tincæ being plainly perceptible at its anterior end—the neck of the uterus appearing to lie between the tumour and perineum, horizontally upon the latter. On carrying the finger around towards the left side, it fell into a sulcus apparently between two tumours, but which Dr. Atlee supposed was caused by the inferior one being the flattened fundus of the uterus occupying that position, and the upper one being an enlarged ovarium. The fundus of the uterus was more evident upon the left than on the right side, and its neck and body appeared to have been curved upon the tumour. The uterus, while the tumour was in situ, was pretty firmly fixed in its position, and did not appear to have been altered in its texture or size, nor was it painful on handling. Dr. Atlee then attempted to raise the tumour out of the pelvis, but it required considerable and continued force before he could effect it. He, however, raised it sufficiently high for his brother to get partially beneath it at the pubic region, and to sustain it while he continued the vaginal examination. The uterus now took its natural position more nearly, became movable, and the finger could be passed between it and the tumour, so as to show clearly that the tumour was distinct from the uterus. Motion of the one did not affect the other, and both could be moved independently of each other. This part of the examination was most carefully conducted both by his brother and him, separately and together, so as to leave no doubt resting upon their minds. There was very little sensibility of the pelvic viscera, and of the tumour in that region. When pressure, however, was made on the anterior part of the tumour in the vagina, it produced a desire to pass water. The bladder occupied this position, and could be distinctly felt. By the examination per rectum, the tumour could not be felt immediately on introducing the finger, but after passing it up a short distance it came against a solid convex tumour, which appeared to rest firmly against the sacrum. Beneath this tumour, and lying against the anterior wall of the rectum, the fundus of the uterus could be felt, and when the tumour was elevated, the finger could be passed between the two, and, in this position, also, both were movable independently of each other. In a standing posture, which caused the pelvic viscera to descend more against the perineum, the bladder, which contained a little water, was pressed before the tumour, and could be felt like a small purse resting against the posterior face of the pubis, with the tumour above and behind it. The case was regarded as one of ovarian disease, but, as there existed some doubt upon the subject, the operation was deferred for a time, and after the lapse of a month, during which nothing whatever had been done, a fresh and more extensive examination was instituted. After examining the tumour per vaginam et anum, Dr. Atlee introduced a sound into the bladder; but instead of passing up anteriorly to the tumour, it kept beneath it, going back horizontally and parallel to the perineum, so that it could be swept from side to side over the inferior convex surface of the tumour, showing that the bladder was beneath it, and that it was impossible for this organ to be lifted by distension above the pubis, being prevented by the weight of the tumour. He also, at the same time, endeavoured to pass a sound into the os tincæ, but, finding that it would not readily enter, desisted. It was very evident, however, in this examination, that the upper part of the tumour occupied the right groin, the posterior part rested on the promontory of the sacrum, its anterior portion on the symphysis pubis, and its inferior portion dipped deeply into the pelvis, so as to form a kind of stopple to the brim of the pelvis, and press down the pelvic viscera against the perineum. The tumour had increased in size, was rather more movable, and, in his opinion, free from adhesions. So far as Dr. Atlee and his brother were able to judge, through the thick, undistended walls of the abdomen, and the simultaneous examination *per vias naturales*, they were of opinion that the pedicle might be an inch or over in length. From the period of her first examination, she was much less troubled with her water, the elevation of the tumour out of the pelvis at that time appearing to have relieved her, by removing its pressure from the bladder. This relief was permanent. The case was, consequently, considered by both Dr. Atlee and his brother as suitable for an operation, to which the patient gave her consent, after its dangers, &c., had been represented to her: it was, accordingly performed on the 28th of August, in the past year, at 11 a.m., in the following manner, the operator being principally assisted by his brother. He began by making a bold and free incision, about eight inches long, from the umbilicus to the pubis on a line with the linea alba, cutting through the skin, a thick layer of adipose tissue, and the sheath of the recti muscles, until he exposed the peritoneum, beneath which he could see the folds of the intestines. Then pinching up the peritoneum carefully between his thumb and finger, he nipt it open with the scalpel. Through this opening he passed a grooved director, and, with a curved probe-pointed bistoury, he slit open this membrane above and below to the extent of the outer wound. As soon as an opening was made into the peritoneum, most of the small intestines, several inches of the transverse colon, and a portion of the omentum, gushed out, and gave a great deal of trouble during the subsequent stages of the operation. The bowels were of a brownish cast, tolerably vascular, and considerably distended with wind. There also issued from the cavity of the abdomen about four ounces of thin transparent serum. His brother now took charge of the bowels, but found it very difficult to keep them out of the way. Indeed, it was utterly impossible to retain them within the abdominal cavity, and all that could be done was to hold them to one side while the operation progressed. The tumour was found occupying the right side, and dipping deeply into the pelvis, and, upon passing an index finger of each hand on either side of the tumour, until he got them rather under it, he was enabled, by using considerable force, to elevate it from its bed and slip it out of the opening, which was merely large enough to permit its escape. Although the tumour was now entirely dislocated, it was still held firmly down by its attachment so as to block up the wound; and this, with the mass of intestines lying out, so obstructed the cavity as to render it exceedingly difficult to survey the pelvis. Dr. Atlee, however, insinuated his finger alongside of the tumour into the opening, and the first thing he encountered was an immense pedicle running from the tumour to the right side of the uterus, about one inch and a half in length. This, for a moment, startled him. In order to examine the state of things, and that he might decide upon the propriety of severing so thick an attachment, he seized the tumour and made gradual, but firm, traction, so as to elevate it and the adhering uterus to view. This was accompanied with some manifestations of pain, great distress in the back, violent neuralgia of the thighs, and considerable gastric disturbance. The tumour now being sustained by an assistant, the pedicle was found to be a very dense, solid, thick, vascular mass, about two inches in diameter in a perpendicular direction, and one and a half inches thick in the antero-posterior diameter, rather diminishing as it approximated the uterus. It was determined to cut it, and he accordingly transfixed the pedicle close to the uterus with a needle doubly armed with a three-stranded silk ligature well waxed. The needle having been cut out, two ligatures remained, in order that each might embrace half the pedicle. In tying the anterior ligature, however, the resisting elastic pedicle relaxed the first knot, and thus showed Dr. Atlee that too much care could not be observed in this part of the operation. He, therefore, employed additional and continued force upon the strands, and one of them snapped. He replaced it immediately with the other ligature, and having drawn the first knot very tightly, an assistant kept it from yielding by pressing firmly upon it with the point of his finger, until it was perfectly secured. Another needle, similarly armed, was passed through the pedicle near the same place, so as to include a small segment of the circle of the first ligature. The half of this ligature was secured in the same way on the posterior portion of the pedicle, while the two ends of the other half were permitted to hang out of the wound, the pedicle being suspended in its loop, to serve in raising up the severed pedicle in case of hemorrhage. In transfixing the pedicle, the greatest

care was requisite to prevent the bowels being wounded by the point of the needle. Dr. Atlee, therefore, adopted the precaution of passing the left index finger down behind the pedicle, and receiving the point of the needle upon it; he kept it thus shielded until it was drawn out beyond danger. In order to make things doubly secure, a four-stranded ligature was thrown around the whole pedicle midway between its transfixed portion and the tumour, and tied first with a single knot, which was kept from slipping by grasping it in the fingers, and then again made to encircle the pedicle, and carefully secured. The pedicle was then severed close to the tumour. At this instant a gush of blood took place from the cut surface—it was the strangulated circulation of the tumour, amounted to from two to four ounces, and was the only hæmorrhage that occurred. The tumour being removed, the cut surface of the pedicle was examined; and although innumerable vessels, with open mouths, showed themselves like the pores of a sponge, not a single drop of blood escaped. The great mass of intestines which were out, and occupied the whole wound, prevented them from seeing into the cavity of the pelvis. Besides, the pelvis was unusually deep. Dr. Atlee made, however, a careful examination of it with his finger, and considered the uterus and left ovary perfectly healthy in every respect. He also felt the fundus of the bladder, which appeared to contain a small quantity of fluid. After removing the coagulated blood, and cleaning the surfaces with a soft sponge, he endeavoured to replace the bowels, but could not succeed, the cavity being, apparently, too small to receive them. He at length transfixed the two lips of the wound at the centre with a sewing needle, and secured them with a twisted suture. Then, every inch, from that point upwards, he applied a similar suture, retaining the intestines and omentum carefully at each point of application, until the upper half was thus secured. His brother supported, with the palms of his hands, the intestines that remained out of the inferior part of the wound. Just at the time of completing the upper portion of the wound, violent efforts at vomiting supervened, the diaphragm and abdominal muscles acted powerfully, producing a great expulsive force in the abdomen, and caused the bowels to burst out between his brother's fingers while endeavouring to restrain them, and also forced the upper part of the wound into a prominent ridge, with a gaping between each of the needles, through which interspaces he expected every moment to see the bowels rush—a portion of the omentum did escape at the upper part of the wound. During this he supported the closed part of the wound with his hand, and called for twenty drops of elixir of opium, which soon calmed the stomach so that he could proceed in the dressing. In consequence of these efforts producing such a strain upon the wound, he gave it additional security by introducing a hare-lip suture between every two needles already employed. The lower part of the wound was perfectly secured at half-inch distances by the same kind of suture, and the intestines gradually pressed in as he progressed downward, until the whole wound was perfectly secured by fifteen twisted sutures, and so firmly that it would resist the most powerful expulsive efforts that could arise. Considerable care was required in passing the needles through the lips of the wound, to prevent their points becoming entangled in the folds of the intestines and wounding them. The ligatures came out at the lowest point of the incision, and were secured to the abdomen by a strip of adhesive plaster. Adhesive plaster was also laid under the ends of the needles to shield the skin. A fold of patent lint, a compress and a towel-bandage completed the dressings, after which the patient was lifted from the table into bed, and ordered to have, occasionally, a couple of teaspoonsful of cold water. The operation lasted nineteen minutes and a half. The principal symptoms, after those indicating the severity of the shock had passed over, were those of general irritation, tympanitis, and abdominal tenderness which were checked by appropriate treatment. The wound was dressed, for the first time, on the seventh day after the operation, and six of the alternate needles were removed, pieces of narrow adhesive straps being substituted in their stead. The wound had united to a considerable part of its extent. The next day a considerable discharge of pus took place. Four days afterwards three of the ligatures came away. Ten days after that the remaining ligatures were taken away, and the catamenia appeared. The patient returned home four weeks from the date of the operation. The following is the description of the tumour, given by Dr. Atlee:—The tumour weighed one pound thirteen ounces; its several circumferences were one foot seven and a quarter inches, one foot six and a half inches, and eleven and a half inches. The cut surface, from which the pedicle was detached, was two and a quarter inches, and one and five-eighths of an inch in diameter, and six inches in circumference. The tumour was very dense and solid. In cutting it the knife felt as if going through sole leather—it partook, in a very slight degree, of the crackling feel of scirrhus. Dr. Atlee split the tumour through the centre—it had a beautifully variegated flesh-coloured appearance. Its cut surface was studded over with stellated points, the radii formed of alternate whitish and flesh-coloured lines, which also run in other directions, and intermingled with each other under various forms. Small orifices could be seen opening on to these cut surfaces, which were vessels cut across in making the section. The tumour was invested with two distinctly marked tunics—the peritoneal and proper coat, both very closely united, and both dense. The proper coat was less closely united to the surface of the tumour, than to the peritoneal coat. At two or three places these two coats were separated in patches about the size of a finger nail, and looked like emptied blisters. The tumour was nodulated over its whole surface, had a pinkish-white colour, and in its external aspect had all the characters of some specimens of encephaloid degeneration. Large vessels could be traced ramifying under its coats, concentring towards the site of the pedicle, and terminating with open mouths upon its cut surface; one of these vessels was as large as a common sized goose-quill. The tumour was of an uniform structure, no point having softened down. Dr. Atlee would call it fibrous or fibro-cartilaginous.

Extraordinarily Premature Occurrence of the Menstruation.—Mr. Whitmore has detailed, in the *Northern Journal of Medicine*, the following extraordinary, but not singular case:—Among the family of Mrs. M., was a female child who, from a few days after birth, had her catamenia regularly at periods of three weeks and two or three days, until she attained the age of four years and some months, when she died, after an illness of forty-eight hours' duration. She was attended on the occasion by the late Dr. Christie, an eminent physician of Cheltenham, who, for more than a year before her decease, had satisfied himself of the fact. The detailed particulars were communicated to Mr. Whitmore by Dr. Christie, by whose permission he had an opportunity of witnessing the examination of the body. When laid out for dissection, its great development was very striking—equalling that of a girl ten or eleven years of age. The mammæ were unusually large, the mons veneris collapsed, but well covered with hair, the labia pudendi sparingly so, though these organs themselves were of unusual size for a child. The development of the pelvis, and of all the deep-seated genitals, was very considerable; and the lower limbs were proportionately large. The child was of a fair complexion; and her hair, which was of a dark-brown colour, was very plentiful. It is much to be regretted that the secreted fluid was not examined microscopically.

Rupture of the Uterus.—In the *American Journal of Medical Science* is contained the detail of the following interesting case:—A coloured woman was seized with severe labour pains, and the membranes were early ruptured; she remained in this situation for about twenty-six hours, with excruciating pain, attended by a midwife. A physician was called in, who found a shoulder presentation, the arm having descended, and the child low in the pelvis, firmly grasped by the uterus, and the pains still very severe. He bled her freely, gave her an anodyne, and delivered by turning with much difficulty. Thirty-six hours after delivery, Dr. Morgan was called to see her; he found her labouring under obstinate constipation, with soreness and much distension of the abdomen; he ordered a blister to be applied to the abdomen, and, by persevering in the use of strong cathartics, aided by enemas, the bowels were opened after the lapse of four days, they having remained inactive for the ten or twelve days previous. From this period an evident improvement took place; the uterus, however, remained higher than usual, much harder, rather enlarged, and extremely painful on pressure. She continued to improve for ten days, when she was suddenly attacked with violent uterine hæmorrhage, attended with great relaxation of the womb, and prostration of the vital energies. The flooding yielded to proper treatment. About eighteen days after her confinement, Dr. M. learned that she was passing fæces per vaginam, and none by the natural passage. He immediately proceeded to an examination, expecting to find a communication between the rectum and the vagina; but, finding no rupture there, pushed his examination further. About the left fundus of the uterus the patient had complained of much soreness, and on pushing the fingers into that region, a large collection of fæcal matter was discovered. A syringe being introduced, several ounces of fluid fæces were removed. She continued to void her fæces involuntarily by the vagina thirty days, during which time she experienced rapid emaciation. A favourable change, however, shortly took place, and the evacuation of fæces through the uterus ceased. It is three years since the case occurred, and she has had no more children since, although she enjoys connexion as before, and bred rapidly previous to the accident.

Case of Poisoning with Hemlock.—At a meeting of the Medico-chirurgical Society of Edinburgh, Dr. Bennett mentioned the following case:—On Monday, April 21st, a man named William Gow, was brought into the infirmary by two policemen, and was found to be dead. On examination, the following appearances were observed:—Great fluidity of blood throughout the system. In the cavities of the heart only a few small grumous clots existed. The veins on the surface of the brain were much congested. The lungs, liver, kidneys, and almost every organ were also much congested. The stomach was found to be much distended with a pultaceous mass, which consisted of the fragments of green leaves and stalks. The mucous membrane of the stomach was congested, with slight extravasation of blood below the epithelium at its cardiac extremity. Intestines healthy. The body was muscular, and without external marks of violence. On examining the contents of the stomach attentively, it was ascertained, from some fragments of the stalks and leaves which had escaped the action of the teeth, that they were portions of conium maculatum. On bruising them with a solution of potash, the mousy odour of conia was strongly evolved. The symptoms presented during life, according to the account furnished by his friends, were as follow. Shortly after eating the hemlock, want of power was experienced in the lower extremities—he faltered in his joints. After a time he was observed to stagger, as a man intoxicated—he fell on his knees—and perfect paralysis of the inferior extremities was manifested. At this time his intelligence remained perfect; he spoke readily and sensibly to those about him. He complained of having lost his sight. The paralysis gradually crept upwards. There were ineffectual efforts to vomit—he could not swallow—slight movements of the left leg. These symptoms were present two hours after taking the poison, but his intelligence was still perfect. Asphyxia now gradually came on, and he died three hours and a quarter after eating the hemlock. These symptoms fully confirmed the description given by Dr. Christison, of the effects of hemlock and its alkaloid conia as observed by him in the lower animals. Some cases had been related, in which delirium was said to have been present; and others, where death was occasioned, were marked by stupor and coma, as when opium has been taken. Nothing of this kind was observed in Gow; but, on the contrary, gradual paralysis creeping from below upwards, referable to some change produced on the spinal cord, of a nature exactly opposite to that produced by strychnia. Dr. Bennett pointed out how these facts perfectly agreed with the account of Plato and Nicander, of the effects produced by the *Κωνειον*, or state poison of the Athenians. A difference of opinion existed among botanists, as to whether the modern conium maculatum was the *Κωνειον* of the Athenians. From the

effects produced in the case described, he was disposed to believe in their identity.

Hematemesis with Chlorosis.—Dr. Ashwell, speaking of the complication of chlorosis with hematemesis, says, that this last-named disease occurs more frequently than is supposed; and, in connexion with so much pain, fulness, and congestion in several organs, as might appear to justify active treatment. He has seen bleeding, purging, and lead, lavishly employed; but with decidedly bad effect. In four cases narrated, there was anemia, quick, irritable pulse, and excitement, precisely the symptoms of chlorosis, and such as may without difficulty be distinguished from similar symptoms dependent on acute inflammatory disease. The transient neuralgic character of the chlorotic pains, notwithstanding their severity, the amenorrhea, countenance, and pulse, must lead to a correct diagnosis, and to modified general and local treatment. The great indication is, either to establish or to restore the catamenial function, and to attempt the attainment of this point, even by the empirical use of emmenagogues, bad as the practice may be, is less injurious than a full pursuance of the antiphlogistic plan. Bloodletting can seldom be required. On one occasion he visited a chlorotic patient who had been bled from the arm for the relief of thoracic fulness and difficult respiration; she was partially and temporarily relieved. It was thought advisable to repeat the bleeding; and nothing could be more conspicuous than its bad effects. Her prostration of strength was extreme; the breathing was more laborious; and an anasarcous state of the body was universally apparent. Nor is it less important to reiterate the caution against excessive purging, especially where mercurial or drastic medicines are employed. The first object, doubtless, is to procure, by proper aperients, healthy and regular evacuations; but the anemia of the patient must be increased by their undue exhibition—a practice so common that some individuals doubt whether more harm than benefit has not accrued from their use. Let this be as it may, it is quite true, that the evil results of such a plan are not confined to the stomach and bowels themselves; the irritation and flatulent distention of the intestines leading to aggravation of the chlorosis, and to nervousness and distressing sinking, very difficult to be borne; and yet with such an increase of disorders, he has known mercury and aloes persevered in for weeks. So strong is the prejudice in favour of a 'good active purgation.'

Crepitus in the Lung after the Absorption of Pleuritic Effusion.—Dr. M'Donnell, in the *Dublin Journal of Medical Science*, describes several cases in which crepitus was heard in the lung after the absorption of the fluid effused in pleurisy had occurred: In the first case in which he observed it, the pleuritic effusion was attended with extensive bronchial respiration, which, as is usual, gradually diminished as the effusion was absorbed; when, just as it was concluded that the whole quantity of the fluid was removed, a distinct, loud, and sharp crepitus was heard, nearly all over the portion of lung, previously the seat of bronchial respiration. The crepitus gradually became less evident, and finally disappeared, leaving the lung free, and the respiratory murmur pure and loud. He had afterwards other opportunities of examining this sign; but in no instance were its peculiar characters better marked, than in the case of a young woman of a full plethoric habit, admitted into the Meath Hospital under the care of Dr. Lees. On examination, she was found to labour under effusion into the right pleura, extending up as high as the spine of the scapula, and, in addition, she complained of the usual symptoms of this affection. She was treated energetically, and in about a fortnight all trace of the disease had disappeared, except a slight amount of dulness, and, during inspiration, *a sharp and distinct crepitus*, conveying the idea of its being generated immediately on the surface of the lung. It extended over almost every part previously occupied by the dulness, and was not accompanied by any other râle or bronchial respiration. There was no dyspnœa, cough, rusty-coloured expectoration, or pyrexia; yet from the slight dulness which remained after the absorption of the fluid, and the sharp crepitus, it was almost impossible to distinguish the signs from those of pneumonia. In a few days, however, this crepitus gave way to a pure and distinct respiratory sound; the patient gradually improved, and was soon discharged, perfectly free from the least trace of pectoral affection. The next case is that of a small boy, aged eleven, who had laboured under pleurisy of the right side, with effusion, which had undergone absorption, leaving the side quite clear on percussion. On placing the stethoscope on the chest, a dry crepitus was extremely audible; it was only heard on forced inspiration, and was not audible either during expiration, or ordinary inspiration, and was unaccompanied by any other kind of râle. The boy had not, during any part of his illness, exhibited a sign or symptom of pneumonia, and his expectoration had never displayed the least trace of the pneumonic character. When listened to attentively, the sound gave the idea of being formed by the rushing of air into cells partially compressed, and the seat of slight infiltration of thin fluid, and of proceeding from the surface of the lung, as if generated in the superficial cells,—an opinion confirmed by the fact of its being produced only on his taking a deep inspiration. Dr. M'Donnell examined this boy daily for the next five days, and though at each time the sound had diminished greatly in intensity, it still preserved its dry crackling quality, exactly like the dry crepitus of pneumonia. Another instance was that of a strong, healthy woman, about thirty years of age, who was admitted into the Meath Hospital, under the care of Dr. Stokes, with extensive effusion into the left pleura. Previous to her admission she had been attended by Dr. Geoghegan, and the treatment he commenced was continued while in hospital. The dulness extended up to the spine of the scapula, and was accompanied by bronchial respiration and œgophony, but no crepitus or bronchitic râle could be heard, nor had she any of the characteristic symptoms of pneumonia. The bronchial respiration was soon replaced by a respiratory murmur, at first feeble, but it soon became louder and more distinct, and then a well marked, *dry, crepitating râle* was audible during ordinary inspiration, but becoming more evident on taking a deep breath:—it was unaccompanied by dulness, bronchitic râles, friction, or any other abnormal sound, and she had no cough, expectoration, difficulty of breathing, or pyrexia. It continued to present the above characters for the next four or five days, and then gradually disappeared.

Tetanus.—Dr. Newbigging related a case of tetanus at a meeting of the Medico-Chirurgical Society of Edinburgh. The subject was a baker in the Grassmarket, aged 28, married, of sober, industrious habits. On the morning of the 16th February, 1844, when engaged with his usual occupation in the bakehouse, he had occasion to go out into the intensely cold air, to chop wood, while in a state of profuse perspiration. In the evening he complained of stiffness about the angles of the jaw, which gradually increased till the 19th, when the jaw became almost completely locked. Afterwards, the different muscles of the body became affected. The duration of the case was about three months. The principal treatment consisted in the free use of morphia, and the occasional administration of croton oil; for although arsenic, Indian hemp, colchicum, &c., were administered at different periods, no decided benefit was ascribed to them by Dr. Newbigging, nor by the late Dr. Abercrombie, Sir George Ballingall, Sir William Newbigging, and Dr. Duncan, who also saw the patient from time to time. The author concluded his communication by remarking, that there is one point on which all authorities on idiopathic tetanus seem to agree,—the torpid state of the intestines, and the offensive nature of their contents; and this condition is worthy of attention, showing how important must be the employment of well selected purgative medicines in such cases.

Alcoholic Odour of the Fluid in the Ventricles of the Brain.—According to the *Illinois Medical and Surgical Journal*, Dr. Bradley, of Illinois, who was summoned before a coroner's inquest, held on the body of Samuel Page, as a medical witness, was enabled at the post-mortem examination to discover the presence of alcoholic odour in the fluid in the ventricles in the brain. The deceased was found about two miles from the village, in his waggon, with his feet hanging over the foreboard, his body resting upon a bag of grain, and his head upon the bottom of the waggon. He was totally insensible, and his breathing stertorous and difficult. He was taken to a neighbouring dwelling, where he died in about ten minutes. He had been drinking for several days previous, but was not an habitual drunkard. He had left a grocery store a short time previous to being found, partially intoxicated, without mittens or any other "extra over-clothes," though the weather was somewhat below the freezing point. On dissection, six hours after death, dark fluid blood poured forth from the sinuses of the brain, to the amount of eight or ten ounces. The brain exhibited excessive vascular turgescence; in the corpora striata, a small amount of sanguineous extravasation was detected, and in the lateral ventricles some serous effusion. Verdict, "death from apoplexy caused by intemperance." *The effused fluid found in the ventricles yielded strongly the alcoholic odour.* This was so apparent, that it was readily recognised by every member of the jury.

GOSSIP.

Apothecaries' Hall.—Gentlemen admitted Licentiates, 12th July, 1845:—John Foster Williams, Charles Vicary, Charles Houlton Webb, John Mason, John Hayward, John Edmund Brine, John Welch.

Election of Fellows.—Copies of the following circular have been forwarded by the Secretary to all the Fellows, with the date of July 19:—"I am directed by the Council to acquaint you that a meeting of the Fellows of this College will be held at the Hall of the College in Lincoln's-Inn-Fields, on Wednesday, the 30th day of July instant, at three o'clock in the afternoon precisely, for the Election of three Fellows into the Council, in pursuance of the provision of the recent Charter. Notice is also hereby given that the President and Council have received a notice, agreeably with the provisions of the Charter, signed by more than six Fellows, that it is their intention to propose Mr. Montague Gossett, a Fellow of the College, as a fit and proper person to be balloted for as a Member of the Council at the above election." [Mr. Gossot, we believe, will make a very worthy Councillor, but why does he not forthwith call a meeting of his supporters, and announce the principles he is prepared to support if elected. This is surely not too high a compliment to the Fellows who would be glad to know who they really were choosing. Last year they made a small mistake —Ed.]

The wrong way to vindicate Character.—Mr. Wakley, M.P., has been so badly advised as to institute an action for libel against the *Medical Times*, and has obtained damages to the amount of 150*l* Mr. Wakley may be gratified that he has put so much money in his pocket—and the proprietors of the *Medical Times* do not appear to care much for the bleeding, as they say "we are content—we never spent a hundred and fifty pounds more to our satisfaction"—but still the Coroner for Middlesex has not *vindicated his character*. He has only shown that a law framed in a dark age, when free discussion was not tolerated, and which pronounces any thing a libel *that has a tendency* to bring a man, whether good or bad, into contempt or ridicule, has enabled him to mulct a newspaper of 150*l*. The plea of "not guilty," which the defendants were obliged, from the nature of the case, to put forward, excluded by special technical rules a mass of evidence that could have alone enabled the jury to decide whether Mr. Wakley was really an immaculate character. As the matter stood, the jurors had only, according to the theory of the law, to declare the letter published in the *Medical Times*, reflecting upon Mr. Wakley, a libel. Our contemporary, in commenting upon the verdict, observes:—"Mr. Wakley's unfortunate character has been again placed under the care of the law," &c. * * * * Such must ever be the fate of those who, while professing that their object is the vindication of character, deceive themselves by foolishly thinking that the lynx-eyed and jealous public will consider the object accomplished by the victimising or crushing of a truth-telling and fearless journalist.—*World.*

No. 305. **SUMMARY.** July 26.

LECTURES ON DISEASES OF THE HEART.

By D. J. CORRIGAN, M.D., Physician to the Whitworth, Hardwick, and Richmond Hospital, Lecturer in the Dublin School of Medicine, &c.

PERICARDITIS.

This evening, gentlemen, I shall proceed to lay before you the means of cure necessary to be adopted in pericarditis. In speaking of the diagnosis of its first stage, we have seen that at this period the system is labouring under a shock analogous to, but much more intense than that which attends the infliction of a severe local injury. On perceiving this analogy, common sense tells us that the routine of treatment proper for removing the effects upon the constitution in the latter would come in here very properly; and experience teaches us that this common sense suggestion is right; for, when called upon to treat a case of the sort, if you should madly attempt to lower the powers of life, a very trifling abstraction of power from the almost paralysed circulation will quickly deprive you of your patient. I have told you that instances have not been unusual in this stage of the disease when persons have fallen into a fatal syncope merely from the effort of getting up in bed. This will caution you, whenever you find your patient in this very low state, never to be busy in putting him into an erect posture for the purpose of ascertaining by the stethoscope whether he may be labouring under pericarditis or not. It cannot be of the least service, and may produce fatal consequences. Here you must have immediate recourse to the administration of stimulants, such as ammonia, camphor, æther, &c., in doses proportioned to the exigency of the case. Opium in small and frequently repeated doses, taking care to avoid the induction of stupor, or even wine in very large quantities, may be necessary to sustain the flagging powers of life. Never under such circumstances use depletion or antiphlogistic means: the time for doing so has not come until the second stage has set in. Even now you must be cautious in your use of the lancet; along with moderate abstraction of blood by venesection, relays of leeches must be frequently applied to the side, and as soon as these come off they should be succeeded by the application of some strong counter-irritant. Of this class I think spirit of turpentine the best, applied in the manner so often recommended by me when lecturing on pneumonia, bronchitis, &c. This may be used as advantageously in the first stage as in the second; then it will materially help to excite the heart to stronger and more vigorous action, while in the second stage it acts as a derivative, by causing a revulsion of blood from the inflamed pericardium to the surface of the body. Turpentine, when used in the first stage, I reckon superior to other stimulants, such as the acetum lyttæ, as the former produces stimulating effects in an incredibly short space of time, when it would be madness to wait until a blister would produce its stimulation, occupying, as it *should* do, a period of some hours. In the second stage the application of a blister would prevent the frequent application of relays of leeches, a means of cure most important to be attended to. In the second stage, along with the employment of the means just recommended, you must lose no time in having recourse to mercury, administered in such a manner as shall soonest induce its specific effects. Should the bowels become disordered by its internal exhibition, you may direct its external administration, either by frequent inunction on the inside of the thighs or over the chest, while along with these means of employing it, any blister which you might apply should be dressed with unguent hydrarg. Another mode of inducing salivation is by introducing into the axillæ pledgets of tow charged with ung. hydrarg., allowing them to remain there until the mercury becomes absorbed; but the first method, that of internal administration, is the one which I would recommend for your adoption. When salivation is induced, it must be continued for twelve or fourteen days, and sometimes for a longer period.

The same treatment applies to the third stage, or that of effusion. Here you must excite salivation as speedily as possible, having due regard to the powers of your patient's constitution; and you will materially assist the absorptive powers of the mercury by the repeated application of blisters, dressed, when they come off, with mercurial ointment. In addition to these means, you must place your patient on a nutritious non-stimulating milk diet. If, during the convalescence of your patient from the effusion of pericarditis (should your efforts be successful), you should detect *regularly* bruit de soufflet, leading you to suspect that the heart itself is originally affected, your prognosis will require to be very guarded; you must restrict your patient to the mildest milk diet, debarring him from any thing at all approaching to the nature of a stimulant; you must at the same time warn him that unless he comply strictly with your every injunction, in all probability he will be doomed to labour under organic disease of the heart, from which months, nay, years, perhaps, may roll over ere he is restored to perfect health.

FUNCTIONAL DISORDERS OF THE HEART.

I should wish, upon the present occasion, to draw your attention to some functional disorders of the heart. On a former occasion, when speaking of an error very generally believed, that irregularity of the heart is associated with hypertrophy of that organ, I endeavoured to demonstrate to you the erroneousness of such a view. On that occasion I mentioned a fact of common occurrence when the biceps, or any other muscle of the arm may, in an hysterical female, acquire an increase of power so great as sometimes, by its violent contractions, to fracture the humerus. "Yet," I then asked, "would you be justified, from this temporary increase of vigour, depending upon an undue accumulation of nervous energy in the part, to infer that the arm was in a state of hypertrophy, and to take measures for the reduction of this excessive action?" I answered "that you would not." Just the same thing takes place in the heart, and here the inference would be false equally as in the illustration. This excessive action of the heart, so far from being hypertrophy, is, on the contrary, associated with extreme muscular debility of that organ. We find in persons naturally of badly formed chests, and in delicate females, in whom this conformation of chest is induced by tightly-laced stays, that a stronger impulse, and extending over a greater portion of the chest, exists than in persons whose physical powers and congenital formation have been more perfect. We may even find that a small heart in the above cases shall give a greater impulse, and that extending, too, over a greater portion of chest, than a heart of much greater magnitude in a healthier subject. How is this to be accounted for? Very easily. In persons whose chests are not properly expanded, whether from congenital malformation or from adventitious causes, we find that at each impulse a much greater portion of the surface of the heart comes into contact with the parietes of the chest than would be the case were the cavity of the chest properly expanded. From this we see the impropriety of considering every case of irregularity of the heart as being of necessity complicated with hypertrophy of that organ. With these prefatory observations I have to request your attention to a form of functional disorder of this organ which, in a paper published some time since, I have denominated "Irregular Action of the Heart in Growing Persons." The affection is curious, and one highly deserving your greatest attention. I have been frequently consulted on account of this affection by young gentlemen articled to merchants and attorneys, persons who spend the greater part of every day in an office busily employed in writing. I have also often found it attacking young lads from the country, who, being suddenly taken from school and its wild pleasures, are thrust into a Dublin warehouse, there to be taxed very often indeed much beyond what their strength would warrant. The time at which it generally appears is uncertain, varying between the ages of thirteen and three or four and twenty. It depends, in the examples I have cited, on the sudden change wrought in all the habits of the persons attacked by it, who, instead of running about merrily and taking all the wild exercise of schoolboys, are cooped up for ten or twelve hours out of the twenty-four in a dark dingy office, breathing its impure atmosphere in place of the pure air which they were wont to inhale in their days of freedom from all restraint, their muscular system cramped and contracted for want of sufficient opportunity of ample development.

In other cases, we often find it associated with spinal irritation, or, to speak more properly, dependent upon it. Here it sets in with persons of either sex who have shot rapidly into great height, who, in fact, have outgrown their strength, and whose muscular system has not had sufficient time allowed it to develope itself adequately to support, with proper firmness, the extraordinary and quick extension of the spinal column. In these cases it very often happens that the spine is never thought to have anything to do in bringing on the affection in question, until deformity or curvature of the spine unequivocally presents itself. It commonly sets in with these persons at or about this period of very quick growth, and is in general associated with other marks of debility. The patient will tell you that palpitations come on if he run or walk at all fast, that he cannot walk any distance without feeling a sensation of weakness across the loins extending down to the muscles of the legs, which, as in other affections of the heart, are often attacked with cramps, that he bleeds from the nose on making very trifling exertions, and that on such occasions his breathing also becomes oppressed.

In other instances it makes its appearance suddenly

The patient is attacked with night-mare, from which horrible state of feeling he awakes to find his heart affected with violent palpitations; the alarm is given; a medical man is sent for; he thinks (as the symptoms seem to him to portend) that an attack of pericarditis is about to set in, bleeds the patient, and thus makes matters worse than before. After some little time, in addition to palpitations coming on when the patient takes exercise, or is affected by mental irritation, they attack him when at perfect rest, in bed for instance, or uninfluenced by any perceptible cause. Perhaps now they are accompanied by pains shooting in the direction of the heart, *which, on contracting, often conveys to the sufferer a feeling as if it had grasped upon something*, so strong is the force with which it occasionally acts. But, no matter what the loudness of sound, or the force of impulse of the heart may be, the pulse in these cases is always soft, weak, and perhaps more frequent than natural. It would appear as if the heart did not possess sufficient power to propel the blood into the extreme vessels with a degree of force sufficient to render the pulse full. In these cases, the irregularity of the heart's action depends upon an undue degree of nervous energy being transmitted to it, which stimulates it to frequent and violent contractions; and this irregular concentration of nervous energy upon the heart is owing to derangement of the general health, produced by the altered habits of the individual affected. In this disorder you will always find the bowels confined; and you will derive great benefit here from keeping the alimentary canal in a healthy state.

The only diseases with which it could be confounded are, hypertrophy of the heart and contraction of the auriculo-ventricular opening. From both it will be readily and at once distinguished by the absence of bruit de soufflet, which you never find in this instance, no matter how loud the sounds, or how violent the action of the heart may be. It is an affection perfectly free from danger in itself, though, as I have said before, it often is but a symptom of spinal irritation, which is completely unheeded both by patient and physician, in their concern for the more vital organ, until plainly marked signs of this spinal affection make their appearance in the shape of curvature of the spine.

In such cases, our practice must be determined by the amount of mischief present. Here our first step must be local bleeding, either by leeches or cupping, or frequently repeated blisters; these, joined to a tonic plan of treatment, comprise all the items necessary to be adopted by us. In these cases, unaccompanied by spinal irritation, when business will allow of the patient's absence for some time, the unwholesome atmosphere of the town should be changed for the more invigorating air of the country. The constitution should be kept up to the highest degree of tone possible, only falling below that which induces inflammatory action. A full allowance of animal food, adapted in quantity and quality to the digestive power of your patient, should be given, joined to a moderate proportion of fermented liquors. Do every thing in your power to increase the general muscular energy, and, according as this is brought about, the symptoms of irregular action of the heart will cease. Along with this you will prescribe, with very great advantage, a residence on the sea-coast, where the benefit derivable from rambling along the crags and cliffs which oppose the destructive progress of the ocean's power, joined to contemplation of the grand and stupendous scenery so peculiar to the shores of the Irish Sea, will alike tend to invigorate both the corporeal and mental faculties. While speaking of the sea, I must not forget to remind you that sea-bathing is a most powerful auxiliary here to your means of cure, either in the magnificent bath which the hand of nature has fashioned from the waters of the wide Atlantic, or in the less noble, though occasionally more beneficial, substitute which the hand of art has provided for us in the cold or tepid shower-bath. Among the purely medicinal agents which we can employ in the disease, iron affords those from which most benefit is derivable. Of all its different preparations, the tartrate is that from which experience would warrant me to expect the most beneficial results. In order to effect any advantage, its use must be persevered in steadily for some months, in doses of half a scruple three times a day. This or some other preparation of iron should be given for the above period in doses adequate to produce a beneficial effect; while acid. hydrocyanic. or what is still better, aqua laurocerasi, in doses of half a drachm, three times a day, may be given with advantage in controlling the distressing palpitation of the heart. But one of the most beneficial means that we can adopt for improving our patient, consists in tranquillising the mind, and freeing it from all dread as to the ultimately favourable termination of the case. Tell him this simple fact, that the disorder, though an unpleasant, is not at all a dangerous one, and that as to its being finally removed, there does not exist room for a shadow of doubt or fear; but never lead him to imagine that the cure of it will be, by any means, a speedy one. *The contrary is the case, for, under the most favourable circumstances, a period of two or three years, and in unfavourable cases, perhaps, of ten or twelve years, may run over before the cure is obtained.* You can have no à priori conception of the good which is done by quieting the patient's mind in this disease. His mind, unusually sensitive about the result of the disease under which he labours, is, in its present unquiet state, a perpetual cause of irritation, keeping up the heart's irregular action. Remove the groundless cause of this exquisite sensitiveness touching the issue of the disorder, and the diseased actions themselves will, in every case, experience a sudden alleviation, almost magically produced. To sum up the treatment of this affection, recollect that the disorder is one of debility; the way to remove which is by keeping up the muscular energy to the highest pitch of tone, by a proper allowance of animal food, suited in quality to the digestive powers of your patient.

Your purely medicinal treatment will consist in regulating the state of the alimentary canal, and assisting to raise the system to a high degree of vigour by the administration of chalybeate tonics. Recollect that your medicinal treatment is ancillary, in a great degree, to the hygienic. Bear in mind that the disorder has been primarily induced by close confinement in an unhealthy atmosphere, and by a total and sudden change in all the previous habits and amusements of your patient. Restore him to these, aid this grand corrective means by the adoption of the regimen and medical treatment above detailed, and you will in every case have the satisfaction of finding that, according as your patient's debility of constitution gives way to your remedies, the palpitation and irregular action of the heart will cease, leaving your patient in perfect possession of renovated strength and health, the greatest blessing which you could possibly confer on him.

COURSE OF LECTURES ON THE THEORY AND PRACTICE OF MEDICINE.

Delivered by C. J. B. WILLIAMS, M.D., F.R.S., Professor of the Practice of Medicine, and of Clinical Medicine, at University College.

With regard to the causes of fever, bad living seems to predispose individuals to fever in a high degree, and it is a question of great importance whether we may not engender the disease in this way. Whenever the people of a community suffer from wanting the necessities of life, typhus fever is pretty sure to break out, whether by predisposing, and laying them open to the influence of the cause previously existing, or whether it is in itself a sufficient cause, we cannot positively determine; practically speaking, it is the same thing, and it is necessary to guard against it. And the circumstance which certainly promotes the disease, and seems to lead to its propagation, is close and crowded habitations, where a number of persons are closely held together in a narrow compass. Bad ventilation, superadded to poorness of living, is almost sure to engender the fever; and it has been observed that where fever does prevail, the extension of the disease, and its fatality, is greatly promoted by the closeness of the habitations, and a want of attention to cleanliness and ventilation. It is remarkable how the type of fever may become changed by removal from a close and ill-ventilated habitation to the freely ventilated ward of an hospital. Fever patients in close habitations breed a sort of pestilence; and when these very patients are scattered about the wards of an hospital, and removed from one another, so that the sources of contagion are cut off, a highly infectious disease may be rendered comparatively uninfectious. This fact is very much acted upon in the fever wards of hospitals, which are now less crowded with patients than formerly. The same argument, however, may not operate against fever hospitals, where the ventilation is well attended to. Supposing the disease to be infectious, that each individual is a source of it, it is obvious that two will produce double the quantity. It is found that the effect of the fever loses its property by dilution, and there is no proof of its being communicated at a distance of twenty yards. There is great reason to believe that it may be conveyed in clothes, and may be kept there for weeks, or months even. And the fact of importance in regard to this part of the subject is, that this infectious property seems to be decomposed at a high temperature. Dr. Harvey, of Manchester, has found that the infection loses its property at a temperature of 120°; therefore, clothes and other things may be thus purified, by exposing them to a temperature of that amount. Besides contagion, I to have advert to the fact, whether it may be produced from any other causes than infection. Practically speaking, it seems to be produced independently of infection, by close habitations and defective nourishment; but whether these operate as predisposing causes, or there is really infection, cannot be traced, and we have not time to stop to inquire into it. Mental depression, combined with fatigue, has been known to lead to the production of fever. Animal and vegetable effluvia, in the most concentrated forms apparently most calculated to produce disease, do not suffice. It has been found that, near the great sewers of Paris, where the offal of the whole city is collected to be prepared for the purpose of manure, and where the stench arising from the decomposition is almost intolerable, fever does not prevail more than in the other parts of the town. The Poor Law Commissioners have brought to light some important facts in their last reports, that seem to prove clearly that the source of fever is connected with close and ill-ventilated habitations and imperfect food; and we can scarcely resist the argument this accumulated evidence brings with it, that these may prove the sources of fever independently of infection. It has been stated that the inhabitants of a district where infection prevails, escape, while persons coming to the new district are more apt to suffer. It would seem as if the residents became accommodated to it. With regard to many other poisons, they seem to produce the same effect as this. If the individual does not sink under it, the cause may go on for a long time and produce no effect. This may serve to explain many phenomena of the disease in this city and in Paris. The disease, there, is called by some gastro-enteritis, and by others fever; and it is a disease of a febrile character, although accompanied by gastro-enteritic symptoms.

Is there more than one kind of continued fever of the typhus class? Do they differ in their real nature and cause? There is synocha, and the different varieties described under the head of synochus; typhus of a severe form; gravior, mitior; and typhus petechialis; and there are some others: but so far as these give the other characters of continued fever, and are not essentially connected with any one of the complications which may exist in it; and in so far as they may occur in the same epidemic, with the same causes, but varying only in different individuals under the different stages, and appear under the same circumstances, they seem to be only the same thing, and there does not appear sufficient evidence to separate them.

The treatment of continued fever necessarily cannot be a simple subject. It must require considerable circumspection and knowledge. Although the fever is identical in its essential parts, yet we find that its type and its character vary greatly, and therefore practically, in relation to the treatment; it exhibits many and even opposite conditions, so much so that identical as it may be in its causes, we have to study it afresh at each epidemic, because the types of epidemics differ so

much. We have to study each of its changes at each period of the epidemic, as the disease is varied by weather and various other causes; nay, the disease is to be watched in each individual. In the same epidemic the disease will vary in the first instance, being typhoid or congestive; the type may change, and become inflammatory and complicated, though some of the converse symptoms take place; one patient may be affected with fever of the congestive form, and another the inflammatory form; one may present one complication, and another another, and in the same individual the disease may be different; in its cause it may become inflammatory fever or synocha, and afterwards typhus or the converse may take place. We shall understand how to modify the treatment if we refer to the elements of the disease. There is, first of all, a reducing agent, which is the cause of the disease—the poison; but this has local irritating effects, acting now on one organ and now on another; secondly, we have to consider the powers of re-action, which constitute the more permanent phenomena of fever; thirdly, the congestions and inflammations, which arise from impaired circulation and secretion, often complicated with irritation of the parts; fourthly, the altered state of the blood, which arises directly from the operation of the poison, or else from the influence of the poison in stopping the excretions, or in vitiating the processes of excretion and secretion; fifthly, the various irritations which arise from these vitiated secretions, and the mischief to which they are likely to give rise; sixthly, the exhaustion and inanition, the manner in which the nutritive powers and vital functions are suspended during the progress of the fever, and the wasting of the bodily strength; lastly, accidents arising out of the different visceral lesions are to be treated, such as ulceration of the intestines, perforation, diarrhœa, and so forth. From these different elements various complications, and most opposite states, may arise, requiring treatment of the most varied kind; and therefore you will be ready to see that the practitioner who attempts to cure all cases of fever by the same means, although they consist of such different varieties, will be less likely to succeed than he who does not *cure* at all—who leaves the issue to nature. There is likewise good reason to conclude that by some measures fever may be driven off, and these measures are those which excite vigorous action of the muscular system, and increase the secretions freely. Many persons exposed to infection, and who have exhibited the first symptoms, have adopted these different methods of treatment, and have not suffered any further evil effects. When the first symptoms of fever come on, an antimonial emetic and a calomel purgative will often remove the disease; cold affusion has also been used with effect in the earliest stage. The vapour bath has been said to produce similar effects in some instances. In robust individuals we find the same sort of change effected without material interference at all; they show sometimes the slight symptoms of fever, commencing during the prevalence of the epidemic, but the symptoms pass off on the occurrence of free perspiration or looseness of the bowels. When the fever is actually developed, the pulse frequent, the skin hot, and when the vascular system manifests the influence of the poison, there is little hope of stopping the fever; the disease has laid its hold; but although we cannot stop the fever, we may do somewhat in guiding its course and in moderating its effects. Here we cannot prescribe the same treatment as in intermittent fever. There are not those marked changes, for such positive interference; yet there is a period of depression, bad constricted state of the skin, and perverted sensibility, pains in the limbs, great shivering, and great defect of the capillary circulation; at this period, too, the disease is actually pronounced, and no doubt an emetic and warmth to the feet has the effect of relieving the circulation and promoting reaction. Then, when the febrile reaction is developed, and the fever begins to show itself, the treatment must vary according to the amount of that febrile reaction. When the febrile reaction is high, and the patient is plethoric, then there is no doubt of the propriety of depletion, with evacuants and cold affusion. On the other hand, where the febrile reaction is imperfect (which is by far the most common case), the pulse weak and frequent, small and irregular, where the typhoid or adynamic state prevails, and the strength is gone, here blood-letting is obviously injurious in proportion to the amount of the depression present. In the congestive variety, however, some depletion may become necessary. When the internal organs seem greatly oppressed by the quantity of blood thrown into them, and when the healthy secretion does not take place, and the functions of the liver are interrupted by the vascular congestion, and when the brain is oppressed, the pupils dilated, and there is stupor and a suffused state of the countenance, in this form of fever general blood-letting has been found useful; but it is only at the very earliest stage that is permissible. There is this to be feared from it: that in drawing blood from the blood-vessels of the arms when the viscera are oppressed, we may draw blood less from the organ that is oppressed than from the whole system; we may diminish the action of the heart, and the quantity of blood in the system, without materially reducing the quantity of blood in the oppressed organ. I should say, as the result of my own experience, and the observation of many patients for many years past, that we are not acquainted with any cases in which general blood-letting is serviceable in the adynamic forms of fever. If blood-letting is applied at all, it should be applied locally, to remove the blood from the seat of the congestion, and not from the general system. There is no doubt, when congestion has continued long, the tone of the vessels in the organs is lost, and you may draw all the blood from the other parts of the body before you succeed in affecting the congested organ. Cupping is the most effectual local depletion of any, because it has an influence in drawing blood from the neighbourhood of the part. Another means of relieving the congestion is by acting on the secretions. We often see congestions relieved naturally, by something that increases the secretion; and we see that fever comes to a termination on the occurrence of some spontaneous discharge. The medicines most generally useful to act on the secretions are antimony and mercury. Antimony is more depressing in its action, and is more calculated for the inflammatory forms of fever, when the increased action is considerable, its action being on the tonic power of the arteries, and tending to promote the secretion of the skin and free secretion of the mucous surfaces. Mercury is slower in its operation. These different remedies are to be tried in most cases of fever, not in large doses, but in small and repeated doses, taking care that they are neither reducing nor irritating to the stomach. And the class of remedies often highly useful, but perhaps less powerful than those I have mentioned, is saline medicines—saline diluents; they act in a similar way by increasing and modifying the secretions. Yet they may be varied according to the nature of the secretion, and according to the predominance of the reaction or depression that exists. In the inflammatory cases nitrate of potash, which is cooling and reducing, may be useful. The solutions of sulphate of soda, sulphate of magnesia, and tartrate of soda, combined with antimonials, more particularly with aperient salts where the bowels do not act spontaneously, are very serviceable. In the more adynamic states, the salts of ammonia, the acetate, muriate, and nitrate, may be useful. In the intermediate stages of synochus, citrates and tartrates are most useful. These become very good vehicles for tartarised antimony, whenever there is chest complication. Probably salines fulfil another indication: that is in restoring the condition of the blood. In the congestive and petechial forms of fever there is no doubt the blood is very much changed, and how far salines act in restoring and preventing this change we cannot pretend to say. The exhibition of chlorate of potash in the putrid kind of fever is supposed to counteract the decomposition. In some instances it has been found useful to give chlorinated solutions of lime.

Besides these remedies to act on the secretions, by increasing and modifying them, it is usually requisite to remove the bad secretions, and to cleanse the body, inside and outside, as freely as possible. Of the poison of fever there can be no doubt; it has a decided influence in injuring the vital properties, and, by perverting the vital powers, causing offensive matter to be engendered. Thus a person labouring under fever is a source of pestilence not only to others, but to himself; and as he poisons his own effluvia and his own secretions, it becomes a primary indication to remove the excretions as freely as possible. This is to be done firstly on the outside by washing frequently with fresh water, or vinegar and water, or warm dilute chlorinated solutions, and keeping the body in clean linen. The inside is to be washed out, too, and this is to be effected by mild aperients and the salines I have mentioned, and diluent drinks, such as barley-water. Nitro-muriatic acid is very useful on all occasions. Whenever there is any peculiar evolution of fetid gas there should be a free use of chlorine. Creosote may be useful for the same purpose. In the use of these remedies we must be guided by the symptoms, of the case. Purgatives must be avoided, as they prostrate; they may be useful at the first commencement, but after this they should be avoided. When the patient is very weak, we must be satisfied with an evacuation every other day. If the evacuations are bad in colour and fetid in odour, mercury is indicated; the milder preparations are preferable to calomel, because they are less reducing and irritating. The hydrarg. cum creta, Dover's powder combined with mercury, and occasionally a slight dose of castor oil to evacuate the canal. The above remedies tend to remove local congestions as well as the fever itself. The next indications to be considered are those arising from the type of the fever; if it is of the adynamic form, without any marked complication, it is a fit case for the use of stimulants, particularly wine; port and sherry somewhat diluted with water, and ammonia and ether might be given. The indications for the use of these remedies are—weakness, softness of pulse, coolness of the skin (there may be temporary heat, but no permanent heat), and the tongue dry and brown; the first sound of the heart is short, and perhaps the interval between the first sound and the radial pulse is prolonged, showing the want of tone in the arterial force. Dr. Stokes gives an additional indication—where the second sound is actually wanting. Wine should be given frequently, and a little at a time. When a flush comes in the face, wine should be diminished, as the object is not to produce marked excitement, but to support. In the advanced stages it is necessary to combine wine with nourishment as much as can be borne. In some cases beer and porter are preferred to wine, and generally towards the end of the fever bark and quinine may be used with great advantage. In the nervous form of fever, narcotics, of which opium is the chief, are to be used, combined with mild mercurials, and antimonial salines, in small doses. Where there is no tendency to congestion of the brain, anodynes are useful with narcotics. Laudanum, from four to ten minims, or as many grains of Dover's powder, and one-eighth up to one-fourth or one-third of a grain of acetate of morphia.

LECTURES ON THE PHYSIOLOGY AND DISEASES OF THE BRAIN.

By J. BOUILLAUD, D. M. P., M. A. M., Member of the Chamber of Deputies, Professor of Clinical Medicine at the University of Paris, Knight of the Legion of Honour, Physician to the Hospital de la Charite, &c. &c.

LECTURE V.

Meningitis (continued).—Other proofs may be given in favour of the opinion announced in the preceding lecture. Thus, in the immense class of surgical diseases, do we not daily see scratches, contusions, wounds, in short, all the various kinds of traumatic lesions, followed by angéiolencitis, more or less intense, of the lymphatic vessels comprised in the wound, and with it the *engorgement* of the ganglions in which the wounded vessels terminate? When the first stage of this adenitis is passed, without appropriate remedies having been made use of, tubercular matter is generated, and the ganglions are changed into masses, offering all the signs of tubercles. A striking example of this species of transformation happened last year in the ward St. Jean de Dieu, No. 5, where a patient died of pleuro-pneumonia, complicated with albuminuria, in which all the glands of the parotidean and submaxillary regions formed a tumour almost as hard and as resistant as bone; their volume had increased fourfold; when divided, they were found to be com-

posed of yellowish masses of a soft, granular matter, similar, except in colour, to a mixture of coarse plaster with water, on the point of solidification · in some spots they were completely softened, and, by pressure, a yellowish-white pus escaped, offering all the characters of softened tubercles or tubercular pus; all the mesenteric glands presented the same degeneration. If, therefore, in external diseases we observe a species of tubercle developed; if we see it produced incontestably by an inflammatory disorder of the lymphatic glands; if, in fine, we remark that this tuberculisation takes place, as it were, step by step under our eyes in the lymphatics of the external organs; it may be asked, why should it not be concluded, by the closest analogy and the most rational induction, that it is produced in the same way in internal organs?

It would be very fortunate, if all the inductions hitherto made, or to be made hereafter, could show as good foundations as this one; for then medical science would progress with much more rapidity and certainty; true principles would be far more numerous than they are at present, and a great number of facts, isolated, because they have been imperfectly studied, on account of no one daring to raise the mysterious veil in which they were necessarily enveloped whilst medicine was still in its infancy, might then be assimilated, grouped, united, and classed under general laws.

A very great fault in many observers is to imagine, from the inconceivable tendency to see everywhere nought but mysteries and prodigies, that nature acts in a thousand different ways, whilst, on the contrary, we ought always to be deeply penetrated with the fact, confirmed by daily observation, that nothing is more unchangeable than nature's acts, and that nothing is more invariable and fatally identical than the mode of development and the effects of a given disease in the same tissue, in the same organ, or the same system. Thus the result is the same if the affection, inflammation for instance, is left under the influence of the same causes to the sole healing powers of nature.

But what is a tubercle, and what is the relation of cause and effect between tubercle and inflammation of the lymphatic vessels? Tubercular matter is to inflammation of this system what pseudo-membranes are to the vascular; for whenever inflammation attacks the latter, it generates a peculiar secretion or exudation from the internal membranes of the vessels. This secretion is carried off, either entirely or in part, by the blood, mixing with its fibrine, which thus becomes more glutinous, more coagulable, and more plastic, and reveals itself to us under the form of the buffy coat, a real organised germ, a real elementary tissue, which needs but to be grafted on a living organ to become vascular and to live. This takes place in a great many cases—for instance, when it is poured out by the capillaries on the surface of a serous membrane, or in the lacunæ of the cellular tissue, where it is changed into a pseudo-membrane, which, if not absorbed by the efforts of nature alone, or aided by appropriate remedies, is soon organised, and vessels being formed in its substance, is converted into serous or fibrous tissue, as the case may be, which may at a later period itself be transformed by an operation of nature, which we are unable to explain, into cartilaginous, osseous, and even calcareous matter. Again, it is well known that in other affections of the vascular system, especially local phlegmasiæ, the vessels are obliterated owing to the exudation of plastic lymph and the coagulation of the blood. The clots then formed are soon converted into real fibrine, adherent to the walls of the vessels, and in many instances organised, so as to form pseudo-membranes, and even sometimes, owing to the increased intensity of the inflammation, they terminate, like inflamed cellular tissue, by suppuration, as is frequently observed after phlebitis. Finally, when the inflammation goes through its various stages with rapidity, so as to reach suppuration, an exudation or purulent secretion takes place immediately in the vascular system, or rather only in the capillaries, and it is in these cases that primitive purulent effusions in the serous cavities are observed; these are never organised, but act as foreign bodies, which nature constantly endeavours to eliminate by absorption or otherwise.

All that has been said relative to the vascular system is equally applicable to the lymphatic, for there a coagulable liquid circulates as blood does in the blood-vessels; like these the lymphatics in the first stage of inflammation, especially the adhesive, secrete a liquid, which may become organised as a pseudo-membrane, but is of a different nature, since it is nothing more than tubercular matter, the germ of the tubercle, and is identical with the coagulum of the lymph. At a more advanced stage, this substance being agglomerated, may obliterate the lymphatics, be organised and transformed, or suppurate in a mode similar to that already mentioned while speaking of the clots of blood, in nature identical with the pseudo-membrane secreted by the internal membrane of the blood-vessels. In short, as in the capillaries of the vascular, so in those of the lymphatic system, suppuration may take place, though the product—pus—is not quite the same.

This established, I will now proceed to explain the nature of those granulations or tubercles met with on the surface of the peritoneum, pleura, pericardium, and arachnoid, in the lacunæ of the sub-serous cellular tissue, and in the pia mater, during the course of, or after, certain inflammations, especially in individuals of a lymphatic temperament. They are the products of the exudation in the lymphatics, which participate in the inflammation, and which are so numerous in the serous membranes and the cellular tissue lining them; in short, they are nothing more than the analogue of the pseudo-membranes of the blood-vessels; they present characters almost identical to these, may become organised and vascular, and may live in the same manner, and then, as they no longer act as foreign bodies, they may remain many years without giving rise to any sign by which their existence can be discovered. But when organised and living, these products of inflammation may become—and that unfortunately too frequently is the case—the seat of phlegmasia, which may terminate by suppuration, and this is the termination in the great majority of instances. At other times these granulations may be transformed, like false membranes, into fibrous, cartilaginous, or calcareous matter, and while undergoing these metamorphoses they very often are a cause of inflammation in the containing organ in which they were deposited subsequently to a previous phlegmasia, and it is after these secondary inflammations, in which the granulations themselves partake, that suppuration takes place

Having thus terminated the declaration of my opinions on the origin of tubercles, I will now finish what I have to say relative to the pathology of meningitis. The cerebral substance in almost every instance is affected at the same time as the meninges, by reason of its contiguity; a layer, more or less thick, of the cortical substance becomes the seat of congestion, and sometimes appears soaked with blood; at the same time it is less firm, and in some cases even softened. The white substance is likewise congested, and when cut offers numerous red spots; but the diminution in the consistency does not exist, except when the inflammation has lasted some time with considerable intensity, or when the ventricular membrane was the seat of the disease, as in this case the subjacent white substance, like the cortical substance covered by the pia mater, always presents a considerable degree of congestion, and is almost always softened to some depth. What I have just stated of the lesions of the cortical substance, which complicate inflammation of the meninges, is a fact which might, by the most simple reasoning, have been predicted before hand, and without the aid of pathology, for how could we explain the delirium and the more or less intense disturbances of the intellectual faculties in cerebral fever by the existence alone of meningitis?

Professor Graham's work, "The Elements of Chemistry," has been better appreciated in Germany than at home. Translated by Dr. Fr. Jul. Otto, the eminent professor of chemistry at Brunswick, the first edition is already out of print, and we understand that Dr. Otto has just committed to the press his second edition.

PATHOLOGY OF EXPECTORATION.

By S. Wright, M.D., Edin., F.S.A.

Physician to the Birmingham General Dispensary, formerly Senior President of the Royal Medical and Royal Physical Societies of Edinburgh, &c. &c.

Muco-purulent Sputum.—This variety of expectoration is met with in every-day practice. To the inexperienced or incautious physician, its presence is often a source of considerable perplexity. It is frequently discharged in large quantities when there is not a trace of disease in the respiratory organs, and again, when more limited in quantity, it will be the concomitant of fatal pulmonary mischief. Its indications are of much value in diagnosis, but they should never be trusted singly.

Appearances and Qualities.—Muco-purulent sputum is of variable aspect. It is usually of a yellow colour, differently shaded, and variegated with patches or streaks of a transparent, pearly-white, green, tawny, or orange hue. Its specific gravity is very inconstant, but is for the most part above that of healthy mucus or pus taken singly; in scrofulous and cachectic subjects, it is sometimes found much lower; it then has an appearance like that of serum or whey. It is seldom frothy, except upon its surface, and the bubbles disappear after a few hours' rest. It may or may not be offensive; it is occasionally intolerably fœtid. It may be tasteless or sweet, sour, bitter, or saline. Its composition is just that of mucus and pus in combination, and varies only as one or other of these fluids may predominate The proportion of pus is generally small to that of the mucus; but they are sometimes pretty equally balanced, and again, the pus will be in the greater abundance. Of course it answers to reagents, as do mucus and pus. As I have before said, we must not pronounce a sputum to be purulent until we are justly satisfied that it contains pus. To this end it is advisable to employ the chemical and microscopic tests which have already been commented and insisted upon.

Pathognomonic relations.—This sputum is often met with, as I have said, when there are no co-existent signs of local disease. Hoffman mentions the case of a clergyman who expectorated pus for forty years, yet without any disease of the lungs.[1] Similar cases are recorded by Morgagni. Storck says, puriform expectoration often attends upon simple catarrh [2] Baumes, in his treatise on pulmonary consumption, speaks of some females, who, after the cessation of the menses, coughed up pus periodically, yet without any injury to their health, and with no indication of pulmonary mischief.[3] Dr. Young observes, ' it has occasionally, although very rarely, been observed, that after every ordinary symptom of a confirmed consumption, with purulent expectoration and diarrhœa, which has ended fatally, the lungs have exhibited scarcely any appearance of diseased structure, the whole of the matter expectorated having been afforded by the morbid secretion of the membrane lining the bronchi."[4] In various forms of heart disease, when the lungs are in a state of perfect soundness, it is not uncommon for muco-purulent sputum to be continually expectorated. I attended, some months ago, a young female, who for the last eight years had suffered from the effects of pericardial inflammation, and during that time had constantly been discharging purulent sputum. Pericardial adhesions and thickening and shortening of the heart's valves on the right side were discovered after death, and there was slight œdema in the lower portion of each lung, but not a single trace of mischief in these organs or in the bronchi to account for the purulent expectoration. The dyspeptic affections of bilious and elderly people are often accompanied by morning cough and profuse spitting of muco-purulent matter, and in very many such cases no signs of lung disease are detegible. It will sometimes happen, that a sudden attack of dyspepsia, from confinement of the bowels, want of exercise, irregular living, or other incidental causes, will be as suddenly attended with cough and muco-purulent spitting, yet without any appreciable pulmo-

nary disease; and as the dyspepsia is relieved, the accompanying ailment subsides proportionally. The periodical cough to which some chlorotic females are subject, is attended with this form of sputum. During the attack, which usually lasts from three to six days, there is nothing whatever, beyond the cough and expectoration, to indicate that the lungs are disordered. In other cases again, this variety of sputum will be discharged, occasionally, and even constantly, to various extent, without the general health being impaired, or any particular function, except the secernent one, of the lungs or bronchi, being deranged.[5]

On the other hand, muco-purulent sputum is a frequent accompaniment of disease and disorder of the respiratory organs. It is common to phthisis in every stage, but it is chiefly found after the softening of the tubercles. It is met with in the third stage of pneumonia, and in gangrene of the lungs. It is an almost constant symptom of bronchial dilatation.[6] I never saw a case of this kind without such expectoration. In pulmonary emphysema it is very common. It often occurs critically upon acute bronchitis, and as often attends the habitual cough of the chronic variety. Asthmatic subjects are liable to it, no matter what the remote or immediate cause of their ailment.

In exanthematous diseases a sudden suppression of the eruption is often followed by cough and muco-purulent sputum. A stout lad, seventeen years of age, caught the itch. It lasted five or six days, and then disappeared quickly, and without the use of remedies. He was immediately seized with cough, attended by muco-purulent expectoration, that continued for nearly a month, during which time his respiration was quite natural.[7] A sudden check to the progress of scarlet fever is sometimes followed by similar consequences. It is more frequently the case with measles,[8] but most of all with small-pox. Great as is the danger attending the suppression of variolous eruptions, there is little to fear if a copious muco-purulent expectoration set in. Such cases are almost invariably favourable in their termination.

This variety of sputum, again, has been known to follow suppurative inflammation, whether arising spontaneously, from operations, or from injuries.

The discharge of this sputum may be either casual or critical. It may subside suddenly or slowly, or may pass into the "thin acrid" or "opaque mucous" variety.

Local Symptoms and Physical Signs.—As muco-purulent sputum is sometimes expectorated when there is no disease whatever of the respiratory organs, so it will be understood that its presence is not always indicated by corresponding signs of local disorder and lesion; and for the same reason it is often not accompanied by any general symptoms which denote impaired health. It does not necessarily, therefore, point to the existence of mischief in the system, or in any part of it. More frequently, however, it is connected with certain other conditions, which, with itself, serve as faithful guides in diagnosis. Percussion sometimes discovers dulness in the lower portion of one or both lungs, and more rarely circumscribed spots of dulness in the middle and superior portions of the lungs. But as a rule, percussion elicits only normal sounds. Auscultation at one time detects pectoriloquy—at another, bronchophony—in a third case, a crepitating râle—and in others, sibilant, sonorous, mucous, or grating rhonchi. Of course, the breath-sounds are as various as the local diseases from which the expectoration may arise. Nor is it necessary to add that the general symptoms are as variable also.

Pathology.—When muco-purulent sputum is unaccompanied by any other signs of lung disease or disorder, it would appear to be dependent upon simple irritation of the lining membrane of the trachea and bronchi. In this manner do we account for the idiopathic affection, as also for its occurrence sympathetically with remote organs that are irritated or diseased—the stomach, or the uterus, for instance. It is neither more nor less than a perverted secretion, and mere irritation of a mucous membrane is quite sufficient under certain circumstances, to give rise to it. In other cases, again, it will be the offspring of inflammatory action, more or less severe, and its appearances and qualities will vary with the degree of inflammation, and with the health and strength of the patient. Thus, in bronchitis, in pneumonia, and in cases of tubercular excavation of the lungs, in one example, genuine pus will be discharged, and in another, nothing but a foul corrosive ichor. In the same subject, even, the sputum will often vary to a great extent, and very rapidly. When this sputum is discharged as a consequence of the sudden suppression of eruptive diseases which do not lead to purulent deposits, or to the generation of pus in the system, it is doubtless owing to that irritation or inflammation which mucous membranes are apt to suffer from, sympathetically with disordered functions of the skin. When, on the other hand, it arises from an arrest of, or an imperfect development of, the pustular eruption on the skin, in cases of purulent exanthemata, it is obviously the morbific matter of the blood diverted from its proper course and the function of the mucous membrane then, is vicarious of that of the skin. When it occurs as a sequela of injury, amputation, or abscess, it indicates the absorption and transition of purulent matter. In such cases, the expectoration is generally curative; whereas, if the matter, instead of being discharged by a secreting surface, be re-deposited, the consequences are for the most part fatal.

The appearances presented by the trachea, bronchi, and lungs, in fatal cases of muco-purulent expectoration, are often in no essential degree morbid. But more frequently we observe an unusual paleness, or œdema of the mucous membrane; again, there will be slight ulceration of it, and vascularity more or less intense and diffused.[9] The lungs may be simply œdematous, congested, hepatized, gangrenous, or penetrated with cavities.

Treatment.—In desperate cases, and where there is much structural lesion, the treatment of course can be only palliative. And it is best under such circumstances that the measures employed should be as mild and as little troublesome as possible. When the expectoration is critical of acute disease, or vicarious of the function of some organ, it should rather be encouraged than checked, but the safest plan is not to interfere with it. If it arise from sympathetic irritation, local means may be used, such as counter irritation, and the respiration of the vapour of hot water, at the same time that treatment is directed against the remote cause of the disorder. When it proceeds from idiopathic irritation, according as this arises from relaxation, or congestion, or has a tendency to run on to inflammation, should the local treatment be energetic or mild. The vapour of hot water may be respired either alone, or in combination with opium, henbane, camphor, chlorine, or iodine. According to circumstances, may one or other of these be added to the water. Counter irritation, with blisters or rubefacients, should be tried. I have often known sponging with cold salt water to do good. For general treatment, the tonic plan is preferable. Quinine, sulphate of zinc, and muriate of iron, are good remedies. In old subjects I have given copaiba with benefit, and I have seen more than one intractable case cured with antimonial emetics.

PURULENT SPUTUM.—This variety of expectoration is less frequently met with than that last described, and like it, also, may accompany the most serious disease, or the simplest disorder, of the respiratory organs.

Appearance and Qualities.—In its purest form, this sputum is is neither more nor less than genuine pus. It is distinguished from "muco-purulent sputum," in that it is almost always expectorated alone; at least, however, it is very rare to find it accompanied by mucus, and when such does happen, the mucus is not, as in the preceding variety, in intimate intermixture with the pus. If they chance to be discharged together, they are very obviously distinct in the spitting vessels, but it is more usually the case that they are expectorated singly.

The appearance and qualities of genuine pus have been already sufficiently described to render a repetition of the description unnecessary in the present place. The purulence of sputum must be determined by the microscope, and by the chemical tests which I have before mentioned. The microscope, however, is the more certain, for it often happens that when pus is tinged with any colouring matter, the action of chemical reagents upon it is somewhat modified.

Purulent sputum may be variously coloured; an intermixture with blood may give it a red, brown, or black hue; and bile and other foreign matters may tinge it yellow, orange, and green, of all shades. But it is usually met with of a light yellow or cream colour, smooth, diffluent, and free from frothiness. Its odour is generally like that of fresh meat, but it is often devoid of smell; and again, it may be excessively offensive, as in gangrene of the lungs, in expectoration from a vomica, wherein the matter has been long pent up, in discharge of the fluid of empyema by the lungs, &c. So also may expectorated pus be neutral, acid, or alkaline, to test paper, and may be tasteless, bitter, sweet, mawkish, or sour. This sputum varies much in density; the better the pus the healthier it will be, and conversely. In debilitated, cachectic, and scrofulous subjects, purulent sputum is often very thin, watery, and acrid. Under such circumstances it is frequently mistaken for "serous sputum." Two tests easily distinguish these fluids. If heat be applied to the thin variety of purulent sputum, it causes merely an irregular and imperfect flakiness, whilst if the same heat be applied to "serous sputum" it will coagulate the greater part of it. The former, again, when viewed under the microscope, shows a greater or less number of stray pus globules, of all sizes and shapes, and an endless variety of torn and shrivelled pus envelopes, pus granules, &c.; none, or at least very few, of which things are met with in "serous sputum."

Purulent sputum is seldom critical; it is generally constant whilst it lasts, and, if cured it either ceases entirely, and without the succession of other expectoration, or it passes into the "thick opaque" or "thin mucous" variety.

Pathognomonic Relations.[10]—This sputum is often

[5] The sputum of phthisis is often exceedingly acrid. It inflames and corrodes the parts whereon it lodges, and excoriates those over which it travels. The air passages, and the mouth and lips of consumptive patients are often abraded by it. If swallowed, it will bring on diarrhœa or dysentery, and not unfrequently inflammation or ulceration of the bowels.

[6] Laennec speaks of a case of dilatation of the bronchi, in which an expectoration of pus alternated with that of puriform mucus.—"On Diseases of the Chest," translated by Dr. Forbes, p. 3., Andral says, a very abundant puriform expectoration generally prevails in dilatation of the bronchial tubes.—These. pp. 29—30.

[7] "Bennet mentions a case of psora, which remained obstinate until an expectoration took place, and was then relieved."—Young on Consumptive Diseases, p. 46.

[8] There is a case related by Lieutaud of a child dying "full of measles," whose bronchi were found loaded with purulent fluid; nor were the lungs free—"pulmonibus inculpatis,"—Hist. Anatomico-Medica, Lib. 2, Obs. 4.

[9] Lieutaud, in describing the *post mortem* of an individual who had died with the symptoms of a mere cough, says—"Tubus trachealis extus œdematosus videbatur. Ejus facies interior levi phlogosi correpta materia crustacea obtegebatur. Bronchiæ et vesiculæ pulmonales pure scatebant, etsi intacta erat pulmonum substantia." Hist. Anatomico-Medica. Lib. 1., p. 1—4. This same author, in his work on the Practice of Physic, records a case in which the bronchi were found full of pus or puriform mucus, yet the lungs were sound. "Comperiuntur bronchiæ muco glutinoso vel pure concreto infarcta, vasa circa hæc reptantia plus æquo turgida varicosa."

[10] Under this head I have stated, a little further on, that pus is sometimes expectorated in consequence of the bursting of an hepatic abscess into the lungs. The following very remarkable case in illustration is recorded by Stalpartius:—"Ipse olim cum D. *Theod. Liebergen*, Medic. Doctori celeberrimo visitavi quendam *Joh. Henrici* nobilissimi D. *Quintini de Veer*, Balivi (quem vocant) quondam Hagiensis ministrum, qui diu de latere suo dextro sub costis nothis conquestus erat; unde suspicabamur, postquam alias satis intellexeramus circum-

discharged when there are no co-existent signs whatever of pulmonary disease. It is sometimes met with in females, during and after the "change of life," yet without any local disease to account for it. Baumes, in his "Treatise on Pulmonary Consumption," speaks of some females who, after the cessation of their menses, coughed up pus periodically, but with no manifest injury to their health. More rarely it is observed in young females to be apparently vicarious of the menstrual discharge. In "Les Ephemerides des Curieux de la Nature" is the case of a woman who had a monthly expectoration of pus amounting to upwards of three pounds. Van Sureten mentions a striking case of purulent expectoration, in which a *post mortem* showed the lungs to be perfectly sound. "Tamen fatendum est, non semper inveniri in phthisicorum cadaveribus pulmones consumptos, licet quotidie ingens sputi purulenti copia prodierit, et hinc medici suspicati essent, viscus illud totum fere contabuisse. Lubens fateor, mihi hoc aliquoties contigisse; et memorabilis talis casus in noscomio practico Viennensi visus est (De Haen "Rat. Medend. I." p. 118, II. p. 620) ubi post sputa purulenta copiosissima pulmo satis integer inveniebatur; undique quidem accretus pleuræ et pericardio in sinistro thorace; sed quomodocumque dissecaretur, nec guttula puris, nec vomicæ vestigium, inveniebatur: in trachea incisa tamen quid purulenti aderat."[11] Dr. Badham has recorded an instance of purulent expectoration during bronchitis, "and the patients had also the symptoms which attend the formation or absorption of purulent matter; he had rigorous regular exacerbations of fever every evening, and sweated profusely, yet the lungs were quite sound."[12] Pus may be derived from the trachea and bronchi, and may continue to be discharged for an indefinite time without any structural disease or disorganisation, as Galen,[13] Willis,[14] and Schenk,[15] tell us. In simple bronchitis the expectoration of pus will often be enormous, perhaps amounting to two or three pounds in the day; yet such cases will recover, and leave no vestige of mischief. It is chiefly observed in the chronic variety of the disease, but sometimes in the acute. Occasionally, the matter will be discharged profusely and with a gush, as though a vomica had suddenly burst, or the pus of empyema had found its way into the bronchi, and yet no rupture of parts may be detergible. Laennec says, it is observed in pleuritis, when there exists no communication between the pleuritic cavity and the bronchi.[16] In the severer forms of bronchitis, terminating fatally, and with various structural disintegration, purulent sputum is often met with. In dilatation of the bronchi and in emphysema pulmonum it is sometimes discharged, but less frequently than the "muco-purulent" variety. In subacute and chronic pneumonia it has been seen, and it is one of the most distinguishing characteristics of the third stage of acute pneumonia. It occurs consequently upon the rupturing of a pulmonary abscess, and may also follow the bursting of an hepatic abscess into the lungs, or the discharge into them of the matter of empyema;[17] in the two latter cases the pus is mostly of excessive fetor.[18] It is most frequently met with, protractedly and in profusion, as the secretion of the lining membrane of a tuberculous cavity. It sometimes succeeds the suppression of pustulous exanthematous eruption, and has been known to be discharged as a metastasis of the remote absorption of pus.[19] It has also followed the sudden stopping of an issue, and the spontaneous healing of chronic ulcers.

Local Symptoms and Physical Signs.—This expectoration is, of course, always accompanied by a cough, but it sometimes happens that there are no other symptoms either troublesome or dangerous. These cases are those in which there is no pulmonary disease or lesion. The cough in such instances is generally not very frequent, and only excited by the presence in the air passages of pus, which having been expelled, the cough ceases. The cough is mostly of a clear, ringing, urgent kind, whilst, in other cases of purulent expectoration, as in bronchial dilatation and tuberculous cavities, it is heavy, labouring, and hollow, and often not connected with any necessity or ability to expectorate. In some examples, the sound of the chest on auscultation and percussion is perfectly natural, with the exception of now and then a little irregular bubbling ronchus in the course of the bronchial tubes, the proper vesicular murmur of respiration being heard at the same time. In other cases, again, the stroke-sound of the chest may be dull in places, or over the entire of the lower portions, with a crepitating or a sharp mucous râle superiorly, or there may be bronchophony, ægophony, metallic tinkling, or pectoriloquy. Mucous râles of every intensity, variety, and duration, are also met with,—so numerous are the functional and structural derangements of the bronchi and lungs which purulent sputum accompanies. There is sometimes considerable pain and soreness in the trachea, and a sense of heaviness in the chest, aggravated by coughing. The voice may be unusually grave, or shrill, or husky, or totally lost. The breathing is generally more or less oppressed, even when there is no physical disease or disorganisation. There is seldom any fever except hectic.

stantias, hepar male se habere: cum vero ille aliquoties sputa purulenta per os tussi egereret, nec ulla sese affecti pulmonis proderent indicia, toti in hoc eramus, ut, unde pus progrederetur, expiscaremur. Quod tamen tum demum nobis scire licuit, cum aperto cadavere, præsente fratre meo quondam carissimo *Joh. Stalpartio vander Wiel*, ingens nobis apparuit Jecoris abscessus, simulque vidimus illud inferiori diaphragmatis parti ad latus dextrum, in pectore autem pulmonem ad idem latus superiori diaphragmatis parti adhærere, et accretum esse, ita ut pus è dicto abscessu per fistulam quandam illo loco diaphragma perforantem ex hepate in pulmonem haud difficulter transire, atque ita ejus pars tussi egeri potuerit."—(Observat. Rarior. Med. Anat. Chirurg. 1687, tom. i. p. 202, Obs. XLVI.)

[16] On Diseases of the Chest, translated by Dr. Forbes, p. 449. Andral says, in a case of a *sudden* evacuation of pus, we are not able to affirm that the liquid evacuated has proceeded from the cavity of the pleura, for it is equally able to proceed both from a vast tubercular excavation, from which there is suddenly an opening into a bronchial tube, or from the mucous tissue of the bronchi themselves. —Thesc. p. 56—7.

* "Mr. Abernethy mentions the cessation of a purulent-like discharge from the lungs, to the extent of more than a pint daily, on the removal of a diarrhœa by calomel and opium. Perfect recovery followed."—Law on Derangement of the Digestive Organs, 2nd Ed. p. 188.

[17] A case of empyema, in which the purulent expectoration was enormous, is related by Dr. Pitcairn in Transactions of Med. Chir. Society of Edin. page 2.231.

[18] This is a rule, and a tolerably correct one too, but it is liable to some exceptions. These exceptions are chiefly met with in instances of evacuation of pus from a vomica, but they are sometimes found, and unaccountably, when the pus is secreted entirely by the lining membrane of the bronchi, and conversely, the pus of empyema is occasionally met with free from fetor. I can only point to a solitary case in my own practice, and I believe the occurrence to be rare in the extreme. Andral, however, seems to have more often remarked it. He says, "the extreme fetor of the sputa, their alliaceous odour, like phosphuretted hydrogen, has been regarded as one of the surest indications that the sputa have had their origin in the pleura. But the sputa of phthisis are sometimes fetid; and we have seen patients whose sputa were inodorous, although we had found in them a communication between the pleura and the air-tubes."—(Thesc. p. 55.) Vater has recorded a case of evacuation of pus from the cavity of the pleura, wherein it had been confined "per integros quatuor annos," yet the matter was free from offensiveness.—Ext. in Haller, Disp., tom. 2, p. 418.

[19] In the Philosophical Transactions for 1702-3, xxiii., p. 1372, Abr. v. 221, p. 1386, Abr. v. 225, is a case related by Dr. Wright and Mr. Cowper of pulmonary abscess succeeding to small-pox, in which pus was freely discharged when the head was placed in a dependent position. A caustic was applied externally, which caused sloughing, and opened a communication with the bronchi. Injections were used successfully, and the ulcer finally healed. It is stated that the lungs were a good deal exposed, and exhibited no sensibility when touched. Slight pressure on the heart caused faintness. Purulent expectoration, on the other hand, is sometimes relieved or arrested by the formation of remote abscesses. In Hautesierck's Collection of Observations is a case in which a purulent discharge from the lungs was permanently suppressed by the occurrence of fistula *in ano*, and another wherein a like pulmonary affection was cured by an abscess of the liver.—Recueil d'Observations de Médecine des Hopitaux Militaires, 1772, p. 286.

ON THE NATURE AND TREATMENT OF SCABIES.

By W. PHILLIMORE STIFF, Surgeon to the Nottingham Union Hospital, Member of the Royal College of Surgeons and University of London, and Licentiate of Apothecaries' Hall.

Writers on therapeutics agree that the number of specific remedies is limited. Chomel states "that mercury, quinine, and sulphur are those only which merit this appellation. To these, vaccine may be perhaps added; but its influence is merely preservative. Remedies can only be termed specific when they act against a disease produced by a specific cause. Syphilis, itch, small-pox, and ague are the only affections against which we know of specific remedies: and should a new specific be discovered, it will be against a disease due to one cause, such as canine madness, or scarlet fever, or measles, and not against a disease like epilepsy, depending on a variety of causes."—*Pathologie Générale.*

During the last six months, I have tested the specific action of sulphur in scabies, and have come to a conclusion at variance with the generally received doctrine. I do not consider sulphur to be a specific. I consider that scabies may always be cured without it, and that it is no remedy when exhibited internally, so as to exude from every pore, and to blacken silver worn in the pocket. The truth of this assertion is rendered more evident by looking into the nature of the disease, and by a physiological consideration of the parasitical animalcule by which it is caused. The class arachnida is composed of mites, spiders, and scorpions; the itch mites, sarcoptes galei, belong to the former division, and, like the class insecta, breathe by ramified tracheæ. They are furnished with four pairs of legs; the two anterior pairs terminate by adhesive suckers, rendering their extraction difficult; the two posterior pairs terminate by setæ, and to these the itching itself is probably due. Breathing, as they do, by tracheæ, it is evident that if we smear them over with oily or fatty applications, their respiration cannot be carried on, and of necessity they become asphyxiated; and it appears to me, that the eradication of the itch mite, when treated with sulphur ointments, is due, not to the sulphur, but to the lard which the unguent contains. This opinion is confirmed by the perfect cure of forty cases, coming under my care during a period of six months, all of which were treated with simple lard, and secluded from other treatment; the average time of treatment was only one week, whilst the common sulphur ointments require a longer period. This mode of curing scabies is quicker, more cleanly, less irritant, and far cheaper than all others. Several remedies, no doubt, act as poisons on the sarcoptes, such as ointment of iodide of potassium, but it is too expensive for general use. The outward application of nitrate of silver is ineligible, on account of the discolouration it produces, and of its positively injurious tendency in cases of eczema, which not unfrequently accompanies scabies. Lard, scented with bergamot, will be found sufficient for the cure, nay, its application was found to be so pleasant by a certain class of patients as to be used as a pommade; a little sesquioxide of iron is still better to disguise it. I have seldom found scabies to be transmitted by touch or by slight contact; in the majority of cases,

sleeping with parties contaminated, or in beds in which they have slept, is generally the mode of contagion. The ova appear to be the medium of transmission, for the disease does not present itself immediately, as would probably be the case if a transference of the itch mite itself took place, but some days elapse before it is noticed. The vesicles are found generally at the flexures of the joints, where great warmth favours the development of the ova, and are seldom, if ever, observed on the face, a part much exposed to cold; or on the surfaces of extension, where the skin is rough and liable to friction; or in the palm of the hand, where the epidermis is thickened. Of the forty patients noted, twenty-three were girls, five boys, six women, four men, and there was no case amongst aged men or women. The more delicate texture of the skin of girls may be better adapted as a nidus for the parasite than that of boys, adults, or aged subjects. On the foregoing principle, I have little doubt but that the treatment of scabies by oily applications is equally applicable to the destruction of other treacheary parasites, such as pediculi, phthuiri, &c.

POISONOUS EFFECTS OF GUANO.

By CHARLES KIDD, M.D., Member of the Royal College of Surgeons, and Physician to the Doonass and Limerick Dispensaries.

The immense interest attached of late to compounds of ammonia in the argricultural world, especially guano, the chief of the nitrogen suppliers, has led me to the conviction that the particulars of the very singular case appended, which occurred within the last month, may not be unattended with good effects, in directing the attention of the profession to a subject at present, perhaps, quite unsuspected, or lead to the observance of more general caution in using this very active agent; the case itself, perhaps, will form the best introduction to the subject.

On Thursday, June 19, I was called to see J. H., a farmer, some three miles from Limerick, who, I was informed, had been for the previous forty-eight hours throwing up blood, and who was now *in articulo mortis*. On arriving at the house, I found him with a large vessel full of dark coloured venous blood, mixed with mucus and saliva, between his feet, while in the intermissions of the deepest prostration he ineffectually attempted to clear the back of the fauces of a thick tenacious, bloody mucus, the greater part being pure venous blood, of which he had now thrown up about four large pailfuls. Struck with the singularity of the matter, I at once questioned the attendants, when I obtained the following history:—He had been to town a week previously for some bags of guano; in his anxiety to get away home, he assisted to fill the bags, and while doing so he held one corner of each of the bags in his mouth. The guano was very dry, and he felt some of the dust of it going down his throat —in his own expressive phraseology, "he felt the fumes and dust of it burning him internally." Returning at night, he complained of his throat; his tongue became painfully swelled, and his lips and mouth excessively sore; he made little of it, thinking it would wear away, but hæmorrhage soon after setting in, he got frightened; by some mismanagement, however, even then no assistance was obtained, and up to the present he had done nothing. On examining the parts, I found the lips and gums exceedingly red and sore; the tongue very much swollen, so as to present a considerable obstacle to an examination of the parts about its base; the posterior fauces also appeared red and swollen, and on examining them over and over again, a gradual exudation of blood took place from some deep source, which we were unable to detect; the submaxillary and sub-lingual glands were somewhat swollen and painful, the swelling extending to the anterior part of the neck, as low as the thyroid cartilage; and, added to these appearances, the poor fellow was troubled with an irritative cough, produced every five minutes, by the blood exuding somewhere about the rima glottidis, if not lower down. Imagining the possibility of something wrong within the chest, I ran the stethoscope over it, but everything seemed quite normal, with the exception of the heart, which plainly betrayed evidences of the drain on the vascular system; the pulse was similarly characterised, being small and particularly weak.

Symptoms of the blood beginning to make its way into the stomach were becoming apparent since morning, as he complained of nausea with tendency to vomit, headache, and general uneasiness; his bowels had also been affected, the dejections being quite black and grumous; he had lost all appetite or wish for anything eatable, and had subsisted for the last three days on some simple acidulated drink; and to complete the sad list of the poor fellow's sufferings, he had not slept for three nights, from fear of suffocation.

From the great necessity which existed to do something at once, I thought first to use pressure on some of the branches of the carotid, or on the vessel itself; the hæmorrhage being manifestly venous, it had no effect. In the meantime I ordered a strong astringent gargle, with alum and creosote, and an acidulous aperient mixture. (Inf. rosæ, sulph. magnesiæ et acid. sulph. dil.) After using the gargle four or five times, the hæmorrhage manifestly abated to a certain extent. The peculiar saline exudation, attended with cough (from the rima, or, possibly, ventricles of the larynx), was more troublesome if possible, so that when flattering himself that the worst was over, more than once, an irresistible effort to cough brought back the hæmorrhage again. The medicine also had a very good effect, and brought away large quantities of blood, acted on by the acids of the upper part of the alimentary canal. The creosote seemed to act very efficiently, but the cough was incessant, as likewise the renewal of the hæmorrhage. I was anxious to try opium; from the great tendency, however, which he evinced for sleep, and which he resisted, fearing suffocation, I was induced to lay it aside.

20.—He was seen to-day by several persons: ever and anon, as the tickling and cough abated, the hæmorrhage diminished. But no combination of astringents that we could devise seemed to have the least effect on the blood coming from the vicinity of the glottis; cough most distressing and constant, at the same time that every thing within the thorax appears quite natural.

21.—Manifestly worse to-day; hæmorrhage uninterrupted. Towards evening the poor fellow shewed some signs of amendment; soon after, however, the pulse became gradually less perceptible; the blood collected in great quantities in the fauces, all assistance became unavailing, and he sunk from complete exhaustion. After death, the blood continued to exude for several hours, till the entire sanguineous system, I should say, had become completely emptied of its contents—a rather singular confirmation of an opinion I had formed, that the hæmorrhage was of a venous character.

I was particularly anxious for a necroscopic view of the organs implicated, but the friends would not permit it. The exact condition of the parts must necessarily be a matter of conjecture. To arrive at something like a conclusion on the point, it would be necessary, perhaps, to enter somewhat into the physiological action of the ammonia compounds, especially with reference to their action on the blood; and see what analogous affection the practice of medicine offers to this very singular case. The poor man was previously quite healthy, indeed, a perfect model of strength and activity, but seemed at once to "break down" under the effects of the ammonia on his system.

The tendency of the pathology of the present advanced state of science is evidently towards an improved "humoralism." It argues much indeed, I think, in favour of the venerable fathers of medicine, that, with all our acquired experience, our intimate familiarity with the most minute parts of the organic mechanism—our refined physiology —our microscopes and micrometers—our modes of analysis, all perfect—that we are insensibly going back to doctrines long considered obsolete, and dignifying with new names, opinions and theories long since laid up in illustrious neglect. Foremost among the modern humoralists, need I say, stand Liebig and Mulder, with the numerous array of their German disciples. John Hunter, however, was perhaps the first who advanced the opinion that the blood was endued with vitality, as much alive, in point of fact, as any other part of the system; a doctrine opposed with much ingenuity by the "solidists," who, with a veneration for the organic scaffolding which we cannot fail to admire, believed, and thought, and wrote, that the initiative and sustaining principle of life existed in the solids; these very solids differing in nothing from the fluids from which they are formed. The phenomena engaged in the formation of blood itself must be familiar to every reader; we shall consider it after its exit from the thoracic duct; in this vessel, experiment would seem to show that the organic globules first make their appearance. On reaching, however, the proper circulatory system, these characteristic indications of vitality become more apparent; they are accompanied in the blood with a certain amount of fibrin in solution, which has a tendency to coagulate and enclose the globules, on any diminution of the vital forces of the system. On the other hand, an opposite condition of the circulating current is readily induced by certain agents of a physical character—soda, nitre, *ammonia*, &c.—an effect which becomes much more obvious in the smaller vessels and capillaries. In the latter, the motion of the red particles becomes retarded; their relative constituents, in common with those of the other components of the blood, become assimilated—identified—each with a particular structure, and the mystic work of fashioning the mighty fabric proceeds. The normal constituents of the blood remain in solution while in contact with living vessels, *coagulation* being merely another name for the death of the fluid. A total absence of fibrin, from any cause, will induce a state of the blood in which coagulation cannot take place; under such circumstances, it becomes incapable of properly stimulating the great centre of the circulation, and death of the entire system soon follows that of the vital fluid. In cases of death from starvation, the blood is found in this uncoagulable condition. J. Hunter mentions that he found it in the same state in a person who died in a fit of passion; and Dr. Copeland gives two cases of hydrophobia, in which he found the blood black, "so fluid in the heart and veins, that it flowed out abundantly from the vessels of the head and neck, and when removed did not coagulate." Indeed, so completely vitiated is the blood in hydrophobia, that I have often thought our utmost skill will continue to be baffled till some one tries *transfusion*, having previously emptied as much as possible the venous system; from the magical effects witnessed in the last stage of collapse in cholera, from throwing saline matters into the veins, I am sanguine about its similar utility in this fearful disease; indeed, it is too obvious that we have entirely lost sight of the extraordinary results of saline injection in cholera, and that in many other affections, where the nervous system is not completely poisoned, it will yet prove of inestimable service.

Of the numerous causes which occasion deterioration of the vital current, there is none, perhaps, more efficient than the action of animal and vegetable effluvia from matters undergoing decay on the extensive but delicate surface of the pulmonary air-cells. Little illustration on this point is necessary; every epidemic of fever, scarlatina, or other infectious disease, affording instances too familiar to the practitioner. The gaunt distortion of the frame, produced by breathing imperfectly oxygenised air to me seemed almost incredible, reading Lord Ashley's harrowing details, till visiting some of the manufacturing and coal districts some short time since, I witnessed, in many instances, some of the hideous ravages of this parent of disease. In many of these *etiolated* beings the blood is in such a dissolved and unhealthy condition, the slightest scratch is followed by intense hæmorrhage; and when they escape from death by accidents, scrofula or phthisis seldom fails to make certain of its hapless victims. Many of the bad effects of ill ventilation depend on taking into the system again excrementitious products previously thrown off from the surface of the lungs or skin, and positively injurious to that nice play of the machinery of life so essential to health. The invisible poison given off from guano differs in nothing, and of its results the case under consideration affords perhaps only one out of the many equally illustrative instances. The pages of phy-

siology teem with experiments on the subject; perhaps those of MM. Gaspard and Magendie are most to the point. These observers state, that in animals they exposed to the emanations from putrid matters, symptoms like those of yellow fever ensued. The blood was found to alter in a most remarkable manner, becoming quite thin, dark coloured, *and exuding from the capillaries* into the different viscera, and even from *the free mucous surfaces*, and when the septic influence was protracted till the death of the animals, the softer solids—the lungs, liver, heart, &c.—were found more or less included in the morbid infiltration. The poison of the viper injected into the veins changes the colour of the blood suddenly into a livid black, the entire vital current quickly coagulating into a mass! and the effects produced with such celerity by four or five drops of strong prussic acid would appear in no way dissimilar; indeed, analogy and experience are quite insurmountable on these points. In every-day practice the same train of phenomena, in a less concentrated manner, is observable. A morbid impression on the myriad ramifications of the nerves of organic life is made, followed by prostration of the vital powers; the innate effort of the system being sufficient to throw off the matter, health is re-established. If, however, the morbid depression be excessive, or if the normal constitution of the blood be altered, the vitiation of the vital current (explain it how we will) goes on increasing; the different secretions necessarily become altered also; the vital current becomes incapable of exerting its normal influence on the viscera; their functional activity becomes deranged, in some entirely annihilated. Some vital organ at length, the brain, or heart, or lung, becomes, in an especial manner, the victim of the encroaching malady, and the patient soon sinks; many dying from a want of proper constitution of blood, it being quite dark-coloured, thin, and watery, deprived of its fibrin and salts, in other words, completely unable to stimulate the sensitive surface of the endocardial membrane and capillaries. The effect of the continued use of alkalis, more especially ammonia, is decidedly to aggravate this state of the system. The only means of obviating it when established, as in purpura, scurvy, and possibly the case under consideration, consisting in tonics, particularly of the acid kind, fresh air, and nutritious materials of the nitrogenised and non-nitrogenised classes.

Several substances, such as gypsum and lime, have been spoken of, to prevent the effluvia from guano in store-houses, vessels, &c. In more than one instance, indeed, such places has been represented as nuisances, and actions at law instituted, as persons in adjoining habitations were incapable of carrying on their ordinary occupations from ill-health. In a case not long since, in which a factory was on the point of discontinuing work, in consequence of the workmen being unable to bear the powerful ammoniacal fumes of a guano store adjoining, the curious power of charcoal to absorb that gas led me to recommend *blocks* of it to be placed about, not *powdered*, as that seems to injure the effect, and we were very well pleased with the result. A more manageable and efficient preventive, however, is obtained, by mixing one part of ordinary bleaching-powder with ten of wet turf mould or saw-dust, and strewing it over the bags of guano; when dry, to be wetted with water containing a small quantity of common oil of vitriol (sulphuric acid). *Gypsum* is also of some use in preventing the unpleasant effects of ammonia; but lime, though sometimes thought of use, merely makes matters worse. Besides ammonia, guano gives off several other ill-defined nitrogen combinations. These are, perhaps, best removed by thorough ventilation; indeed, in every case where exposure to these emanations becomes unavoidable for any length of time, a current of air is the only effectual mode of obviating the deleterious agency to which we have alluded.

Inversion of the Uterus.—Dr. Skae, of Leven, records, in the *Northern Journal of Medicine*, a case of inversion of the uterus occurring at the fourth month of utero-gestation, which produced abortion. The displacement was reduced with some little trouble, and the patient did well.

HOSPITAL REPORTS.

UNIVERSITY COLLEGE HOSPITAL.

Reported for the Medical Times by H. J. M'Dougall, Esq. late House-Surgeon.

John Prior, æt. 61, a coachman, married, and of temperate habits, was admitted into No. 2 ward, under Mr. Quain, on the afternoon of the 30th of May 1845. Twelve months previously, while riding post, he was thrown with considerable violence against the pommel of the saddle; swelling of both testicles followed, but subsided by the use of leeches and fomentations. Since that time has always had some difficulty in passing his urine, increased by exposure to wet or cold, and also by taking any quantity, however small, of stimulant liquors; the stream has been for some time small and forked, and latterly the urine has constantly dribbled from him involuntarily. A fortnight before his application at the hospital, the swelling again appeared after having, with greater difficulty than usual, passed his urine.
